

The background of the cover is a composite image of surgical scenes. At the top, a close-up shows hands in blue gloves performing a procedure. Below this, a larger image shows a surgical team in an operating room, with several surgeons in blue scrubs and masks focused on a patient. The overall color scheme is blue and teal, with a grid-like pattern overlaid on the lower half.

Greenfield's surgery : scientific principles and practice / editors,
Michael W. Mulholland ... [et al.]; illustrations by Holly R. Fischer.—5th ed.
p. ; cm.

Other title: Surgery : scientific principles and practice
Includes bibliographical references and index.

Summary: "The Fifth Edition of Greenfield's Surgery has been thoroughly revised, updated, and refocused to conform to changes in surgical education and practice. Reflecting the increasingly clinical emphasis of residency programs, this edition features expanded coverage of clinical material and increased use of clinical algorithms. Key Points open each chapter, and icons in the text indicate where Key Points are fully discussed. Many of the black-and-white images from the previous edition have been replaced by full-color images"—Provided by publisher.

DISCLAIMER

Care has been taken to confirm the accuracy of the information presented and to describe generally accepted practices. However, the authors, editors, and publisher are not responsible for errors or omissions or for any consequences from application of the information in this book and make no warranty, expressed or implied, with respect to the currency, completeness, or accuracy of the contents of the publication. Application of the information in a particular situation remains the professional responsibility of the practitioner.

The authors, editors, and publisher have exerted every effort to ensure that drug selection and dosage set forth in this text are in accordance with current recommendations and practice at the time of publication. However, in view of ongoing research, changes in government regulations, and the constant flow of information relating to drug therapy and drug reactions, the reader is urged to check the package insert for each drug for any change in indications and dosage and for added warnings and precautions. This is particularly important when the recommended agent is a new or infrequently employed drug.

Some drugs and medical devices presented in the publication have Food and Drug Administration (FDA) clearance for limited use in restricted research settings. It is the responsibility of the health care provider to ascertain the FDA status of each drug or device planned for use in their clinical practice.

To purchase additional copies of this book, call our customer service department at (800) 638-3030 or fax orders to (301) 223-2320. International customers should call (301) 223-2300.

Visit Lippincott Williams & Wilkins on the Internet: at LWW.com. Lippincott Williams & Wilkins customer service representatives are available from 8:30 am to 6 pm, EST.

To my loving family.

—M.W.M.

*To my wife, Cheryl, and our children, Chris, Shannon,
Becky, and Heather for your love and support and to the
surgical residents who have always stimulated me to stay
“one step ahead.”*

—K.D.L.

To my wonderful family: Faith, Kevin, and Megan.

—G.M.D.

*To Lauren, Michael, and Anna, for all you sacrifice
for me.*

—R.V.M.

*Dedicated to the continual pursuit of Scientific
knowledge to improve the lives of our patients.*

—D.M.S.

*To my family, Nancy, Rivers, Walker, Joe, and Antione,
who remains supportive of my vocation as a surgeon*

—G.R.U.

Thomas Jefferson University
Chief
Department of Surgery
Thomas Jefferson University Hospital
Philadelphia, Pennsylvania

Nicholas J. Zyromski, MD

Assistant Professor of Surgery
Indiana University School of Medicine
Indianapolis, Indiana

The editors are pleased to present the fifth edition of *Greenfield's Surgery: Scientific Principles and Practice*. The field of surgery has changed fundamentally in the years since the first edition of this text. Growth in the knowledge base of clinical surgery continues exponentially. Surgical practice has been transformed through advancements in physiologic and cellular investigation, integration of new techniques derived from imaging and robotics, from the concept of patient-centered care, and from the emerging field of biocomputation. The accelerating pace of scientific progress demands rapid adoption of new ideas into surgical therapy and a commitment to lifelong learning. Accordingly, the new edition of *Greenfield's Surgery* seeks to integrate new scientific knowledge with evolving changes in surgical care.

The fifth edition has been enhanced in every way, with changes to the book's editorial board, authorship, content, organization, and visual presentation. The fifth edition of *Surgery: Scientific Principles and Practice* reflects the founding principles and guidance of Lazar J. Greenfield, MD. His perceptive wisdom helped to create a truly unique book that balances scientific advance with clinical practice. With this new edition, we welcome a new editor—Diane M. Simeone, MD. Her expertise, energy, and vision have invigorated this volume.

We have solicited contributions from well over 200 authors, all chosen because of their scientific and clinical sophistication. Each contributor is currently an active practitioner in the field of surgery. Moreover, many have presented seminal articles and developed the new concepts in their disciplines that are featured in the text, for example, the new chapter "Policy Approaches to Improving Surgical Quality." Advances ranging from health services research to endovascular therapy mark the book as truly unique.

Organizationally, the book begins with topics of broad relevance to the practice of surgery, followed with chapters arranged by organ system. Trauma and transplantation are presented in the form of separate sections rather than subdivided chapters. The

content within each has been presented as individual chapters in appreciation of the significance of each topic.

The book has been designed to create a text that not only looks better but also works better. The text is produced in a full range of colors, creating both visual impact and more opportunity to convey information quickly and with greater meaning. We continue our commitment to superb medical art in the form of line drawings—all created by a single artist. These illustrations have been enhanced to ensure a presentation that maximizes teaching effectiveness and clinical utility. Each chapter begins with a series of highlighted key teaching points, which are referenced within the text that follows. Individually numbered decision-making algorithms are featured throughout the book to provide diagnostic and management information in a simplified format. Tables carry classification bars, such as Diagnosis or Results, useful both when scanning the text for information and when accessing the book's contents digitally. The most important articles and chapters on the topic are highlighted in the reference list.

The fifth edition continues to be highly integrated with a new electronic format to provide supplemental educational material. These materials include review questions for reinforcement of concepts and for board examination preparation. Access to supplemental content produced by Lippincott Williams & Wilkins is an additional advantage of this electronic integration.

Today, *Greenfield's Surgery: Scientific Principles and Practice* has become the gold standard text in the field of Surgery. The editors continue their commitment to the education of contemporary surgeons, and to improved care of the patients that they serve. We believe that with the many improvements implemented in this fifth edition, it will continue to be the text by which all other surgery texts are judged.

Michael W. Mulholland, MD, PhD

ACKNOWLEDGMENTS

I express my appreciation for the efforts of the contributing authors, whose scholarship makes this work possible. We have been fortunate to maintain a happy working relationship with our publisher, Lippincott Williams & Wilkins, and I wish to specifically acknowledge the support of Brian Brown as acquisitions editor.

—M.W.M.

My gratitude to John Cameron, MD and the faculty and housestaff of the Johns Hopkins Hospital who both trained me and served as my role models for my career as an academic surgeon. Thanks also to the surgical faculty and housestaff at the Indiana University for providing a constant stimulus for greater achievement. It has been my honor and privilege to work with you over the last several years.

—K.D.L.

I appreciate the efforts of the faculties and residents at the University of Michigan, Washington University, and UCSF with whom I have had the privilege to work.

—G.M.D.

Thanks to the housestaff and students, whose dedication, inquisitiveness, and challenges provide the stimulus and rewards for this effort.

—R.V.M.

To my family: Ted, Samuel, and Amelia.

—D.M.S.

I am grateful to the residents and fellow at the University of Michigan. It has been a joy to train you and be trained by you.

—G.R.U.

Volume 1

PART ONE :

SCIENTIFIC PRINCIPLES

- 1** Reading Effectively to Attain Proficiency in Surgery . . 3
 Richard H. Bell, Jr., Linnea S. Hauge, and Debra A. DaRosa
- 2** Substrate Metabolism in Surgery 9
 Steven E. Raper
- 3** Nutrition and Metabolism 21
 J. Stanley Smith, Jr. and David C. Frankenfield
- 4** Wound Healing 48
 Robert D. Galiano and Thomas A. Mustoe
- 5** Hemostasis 70
 Peter K. Henke and Thomas W. Wakefield
- 6** Inflammation 91
 Matthew R. Rosengart and Timothy R. Billiar
- 7** Surgical Infections 132
 E. Patchen Dellinger
- 8** Shock 147
 Joseph Cuschieri
- 9** Critical Care 166
 Avery B. Nathens and Ronald V. Maier
- 10** Fluids, Electrolytes, and Acid–Base Balance 189
 Richard B. Wait and Reginald Alouidor
- 11** Burns 214
 Nicole Gibran
- 12** Anesthesiology and Pain Management 237
 Sachin Kheterpal, Timothy W. Rutter, and Kevin K. Tremper
- 13** Cancer 261
 Steven K. Libutti
- 14** Policy Approaches to Improving Surgical Quality . . 287
 John D. Birkmeyer and Justin B. Dimick
- 15** Measuring the Quality of Surgical Care 291
 Justin B. Dimick and John D. Birkmeyer
- 16** Patient Safety 298
 Darrell A. Campbell, Jr.

PART TWO:

SURGICAL PRACTICE

SECTION A: TRAUMA

- 17** Trauma and Trauma Care: General Considerations 309
 Ronald V. Maier

- 18** Prehospital and Resuscitation Care 327
 Eileen M. Bulger
- 19** Head Trauma 337
 Randall M. Chesnut
- 20** Maxillofacial Trauma 354
 Richard A. Hopper and Joseph S. Gruss
- 21** Neck Injuries 359
 Saman Arbabi
- 22** Chest Trauma 370
 Thomas K. Varghese Jr.
- 23** Abdominal Trauma 385
 David H. Wisner, Joseph M. Galante, Matthew O. Dolich, and David B. Hoyt
- 24** Genitourinary Trauma 405
 Thomas G. Smith III and Hunter Wessells
- 25** Vascular Trauma 414
 Benjamin W. Starnes
- 26** Orthopaedic Trauma 423
 Jens R. Chapman, Richard J. Bransford, and Carlo Bellabarba
- 27** Pediatric Trauma 431
 Mary E. Fallat
- 28** Geriatric Trauma and End-of-Life Decisions 445
 William P. Schechter
- 29** Trauma in Pregnancy 450
 Amy D. Wyrzykowski and Grace S. Rozycki
- 30** Critical Care and Postinjury Management 456
 Grant E. O'Keefe
- 31** Environmental Injuries 466
 Gregory J. Jurkovich
- 32** Terrorism 486
 Eric R. Frykberg

Volume 2

SECTION B: TRANSPLANTATION & IMMUNOLOGY

- 33** Transplantation Immunology 497
 Jeffrey L. Platt and Marilia Cascalho
- 34** Organ Preservation 515
 Robert M. Merion
- 35** Renal Transplantation 531
 Chris Freise and Peter Stock
- 36** Hepatic Transplantation 542
 Theodore H. Welling and Shawn J. Pelletier
- 37** Cardiac Transplantation 565
 Richard N. Pierson III
- 38** Pulmonary Transplantation 576
 Raja S. Mahidhara, Jules Lin, and Andrew C. Chang

- 39** Pancreas and Islet Transplantation 590
Randall S. Sung

SECTION C: HEAD AND NECK

- 40** Head and Neck 609
Matthew C. Miller, Jeffrey S. Moyer, and Theodoros N. Teknos

SECTION D: ESOPHAGUS

- 41** Esophageal Anatomy and Physiology and Gastroesophageal Reflux Disease 629
Jeffrey H. Peters, Virginia R. Little, and Thomas J. Watson
- 42** Esophagus: Tumors and Injury 666
Philip A. Rascoe, John C. Kucharczuk, and Larry R. Kaiser

SECTION E: STOMACH AND DUODENUM

- 43** Gastric Anatomy and Physiology 685
Michael W. Mulholland
- 44** Gastroduodenal Ulceration 699
Michael W. Mulholland
- 45** Morbid Obesity 713
Rebecca P. Petersen, Christopher J. Myers, and Eric J. DeMaria
- 46** Gastric Neoplasms 722
Rebecca M. Minter

SECTION F: SMALL INTESTINE

- 47** Anatomy and Physiology of the Small Intestine 737
Eric T. Kimchi, Niraj J. Gusani, and Jussuf T. Kaifi
- 48** Ileus and Bowel Obstruction 748
David I. Soybel and Wendy B. Landman
- 49** Crohn Disease 772
Fabrizio Michelassi and Sharon L. Stein
- 50** Small-intestinal Neoplasms 784
Douglas J. Turner, Ajay Jain, and Barbara L. Bass

SECTION G: PANCREAS

- 51** Pancreas Anatomy and Physiology 799
Taylor S. Riall
- 52** Acute Pancreatitis 818
Jason S. Gold and Edward E. Whang
- 53** Chronic Pancreatitis 827
Nicholas J. Zyromski and Thomas J. Howard
- 54** Neoplasms of the Exocrine Pancreas 837
Attila Nakeeb and Keith D. Lillemoe
- 55** Neoplasms of the Endocrine Pancreas 857
Eugene P. Kennedy, Jonathan R. Brody, and Charles J. Yeo

SECTION H: HEPATOBILIARY AND PORTAL VENOUS SYSTEM

- 56** Hepatobiliary Anatomy 873
Richard D. Schulick
- 57** Hepatic Infection and Acute Hepatic Failure 888
Aruna Subramanian, Ahmet Gurakar, Andrew Klein, and Andrew Cameron
- 58** Cirrhosis and Portal Hypertension 904
Michael R. Marvin and Jean C. Emond

- 59** Hepatic Neoplasms 935
Christopher J. Sonnenday, Theodore H. Welling, and Shawn J. Pelletier
- 60** Calculous Biliary Disease 960
Henry A. Pitt, Steven A. Ahrendt, and Attila Nakeeb
- 61** Biliary Injuries and Strictures and Sclerosing Cholangitis 981
Keith D. Lillemoe
- 62** Biliary Neoplasms 998
Sharon Weber, Brett Yamane, and Yuman Fong

Volume 3

SECTION I: COLON, RECTUM, AND ANUS

- 63** Colonic and Rectal Anatomy and Physiology ... 1017
Elizabeth C. Wick
- 64** Gastrointestinal Motility Disorders 1026
Sandra A. Tan and George A. Sarosi Jr.
- 65** Acute Gastrointestinal Hemorrhage 1038
Lawrence T. Kim and Richard H. Turnage
- 66** Ulcerative Colitis 1056
Emily Finlayson
- 67** Colonic Polyps and Polyposis Syndromes 1069
C. Richard Boland and Robert S. Bresalier
- 68** Colorectal Cancer 1090
Arden Morris
- 69** Diverticular Disease 1120
Lauren Kosinski, Kirk Ludwig, and Mary Otterson
- 70** Anorectal Disorders 1130
Bard C. Cosman, Arden M. Morris, Santhat Nivatvongs, and Robert D. Madoff

SECTION J: HERNIA, ACUTE ABDOMEN, AND SPLEEN

- 71** Abdominal Wall Hernias 1159
Robert J. Fitzgibbons Jr., Samuel Cemaj, and Thomas H. Quinn
- 72** Acute Abdomen and Appendix 1199
Jeffrey B. Matthews and Richard A. Hodin
- 73** The Spleen 1212
Douglas L. Fraker

SECTION K: SURGICAL ENDOCRINOLOGY

- 74** Breast Disease 1241
Tari A. King and Monica Morrow
- 75** Thyroid Gland 1282
Barbra S. Miller and Paul G. Gauger
- 76** Parathyroid Glands 1303
Gerard M. Doherty
- 77** Adrenal Gland 1325
John A. Olson, Jr., and Randall P. Scheri
- 78** Pituitary Gland 1345
William F. Chandler, Ariel L. Barkan, and Ricardo V. Lloyd

SECTION L: LUNG NEOPLASMS

- 79** Lung Neoplasms 1359
Andrew C. Chang and Jules Lin

- 80** Chest Wall, Pleura, Mediastinum, and Nonneoplastic Lung Disease 1390
Rishindra M. Reddy

Volume 4

SECTION M: ARTERIAL SYSTEM

- 81** Congenital Heart Disease 1425
Jennifer C. Hirsch, Eric J. Devaney, Richard G. Ohye, and Edward L. Bove
- 82** Valvular Heart Disease and Cardiac Tumors ... 1449
Tomislav Mihaljevic, Craig M. Jarrett, and A. Marc Gillinov
- 83** Ischemic Heart Disease 1462
Jonathan W. Haft
- 84** Mechanical Circulatory Support for Cardiac Failure 1483
Sanjeev Aggarwal, Keith D. Aaronson, and Francis D. Pagani
- 85** Pericardium 1505
Jules Lin
- 86** Vascular Diagnostics 1514
Gregory L. Moneta
- 87** Endovascular Treatment of Disease 1537
Matthew J. Eagleton and Sunita D. Srivastava
- 88** Vascular Infections 1556
G. Patrick Clagett
- 89** Atherosclerosis and the Pathogenesis of Occlusive Disease 1569
Anton N. Sidawy, Robyn R. Macsata, Matthew A. Goettisch, Niten Singh, and Subodh Arora
- 90** Cerebrovascular Occlusive Disease 1584
Peter H. Lin and Tam T. Huynh
- 91** Upper Extremity Arterial Disease 1598
Mark D. Morasch
- 92** Renal Artery Occlusive and Aneurysmal Disease 1608
Gilbert R. Upchurch, Jr., Peter K. Henke, John E. Rectenwald, Jonathan L. Eliason, and James C. Stanley
- 93** Splanchnic Vascular Occlusive and Aneurysmal Disease 1629
John E. Rectenwald, Jonathan L. Eliason, Peter K. Henke, Gilbert R. Upchurch, Jr., and James C. Stanley
- 94** Aortoiliac Disease 1653
Daniel J. Reddy, Mitchell R. Weaver, and Alexander D. Shepard
- 95** Femoropopliteal and Tibial Occlusive Disease ... 1668
William P. Robinson, Matthew T. Menard, and Michael Belkin
- 96** Lower Extremity Amputation 1683
Matthew J. Sideman, Kevin E. Taubman, and Bradley D. Beasley

- 97** Pathogenesis of Aneurysms 1696
B. Timothy Baxter and G. Matthew Longo
- 98** Thoracic Aortic Aneurysms 1706
Gorav Ailawadi
- 99** Thoracoabdominal Aortic Aneurysms 1719
Hazim J. Safi, Anthony L. Estrera, Charles C. Miller III, Ali Azizzadeh, and Dianna Milewicz
- 100** Abdominal Aortic Aneurysms 1733
Thomas S. Huber and W. Anthony Lee
- 101** Lower Extremity Aneurysms 1768
Amy B. Reed

SECTION N: VENOUS SYSTEM

- 102** Venous Disease 1777
Thomas W. Wakefield and Michael C. Dalsing

SECTION O: PEDIATRICS

- 103** Surgical Physiology of Infants and Children 1803
Federico G. Seifarth and David K. Magnuson
- 104** Fetal Intervention 1832
George B. Mychaliska and Darrell L. Cass
- 105** Pediatric Head and Neck 1842
Keith T. Oldham and John J. Aiken
- 106** The Pediatric Chest 1853
Tony Capizzani, Ronald B. Hirschl, and Robert E. Cilley
- 107** Pediatric Abdomen 1884
Thomas T. Sato and Keith T. Oldham
- 108** The Pediatric Genitourinary System 1946
Eugene Minevich and Curtis A. Sheldon
- 109** Childhood Tumors 1956
Barrie S. Rich and Michael P. La Quaglia

SECTION P: GENITOURINARY SYSTEM

- 110** The Pregnant Patient 1983
Cosmas J. M. Vandeven, N. Scott Adzick, and Alexander S. Krupnick

SECTION Q: SKIN AND SOFT TISSUE

- 111** Cutaneous Neoplasms 1999
Michael S. Sabel, Timothy M. Johnson, and Christopher K. Bichakjian
- 112** Sarcomas of Soft Tissue and Bone 2018
Sandra L. Wong
- 113** Plastic and Reconstructive Surgery 2039
David I. Brown, Steven R. Buchman, Paul S. Cederna, Kevin C. Chung, Edwin G. Wilkins, and William M. Kuzon, Jr.

PART ONE

■ **SCIENTIFIC PRINCIPLES**

CHAPTER 1 ■ READING EFFECTIVELY TO ATTAIN PROFICIENCY IN SURGERY

RICHARD H. BELL, Jr., LINNEA S. HAUGE, AND DEBRA A. DaROSA

KEY POINTS

- 1 During a residency in surgery, the successful surgeon-to-be advances from a novice, who must follow rules to achieve good outcomes, to becoming proficient, which means that accumulated knowledge and experience allows him/her to respond correctly to situations in a more automatic and effortless manner.
- 2 Real learning (more than just memorization for the short term) occurs when information becomes stored in long term memory. Learning with understanding occurs when the student or resident has accumulated sufficient knowledge in long-term memory that he/she recognizes familiar patterns in the new situations that are encountered.
- 3 Reading is a critical tool for acquiring surgical knowledge. Reading that leads to deep understanding can be facilitated by conscious strategies before, during, and after reading that increase the likelihood that information will be retained in long-term memory and be accessible when needed.
- 4 The student of surgery can and should develop conscious strategies for assessing the extent to which their reading results in deep comprehension of the educational material.

LEARNING, MEMORY, AND PROGRESSION TO EXPERTISE

If you are reading this book, the chances are high that you will be (or are or have been) a surgery resident on the first day of your first rotation of your first year. Imagine (or remember) the call to the emergency room to evaluate a new patient with a complex problem, perhaps a 70-year-old male with an upper gastrointestinal hemorrhage and known coronary artery disease. By that point in your education as a doctor, you will have learned enough basic rules about resuscitation to take a few steps—check the airway, start an intravenous line, send off blood for a type and cross match, perhaps place a Foley catheter. Soon, however, your knowledge, skills, and abilities are overwhelmed by the complexity of the situation. Perhaps the patient's blood pressure falls, or the electrocardiogram pattern changes. Chances are that you turn at that point to a senior or chief resident, who comes to your aid, seemingly cool in the face of chaos, and makes precise and rapid adjustments in the patient's treatment, develops a rapid differential diagnosis, and orders the appropriate diagnostic testing. Finally, the attending surgeon arrives with an air of confidence born of experience, seems to recognize the problems immediately, and, after an incisive set of questions, makes a decision to take the patient to the operating room. What has happened to allow the senior resident or senior surgeon to achieve that level of competence and confidence?

The beginning of a surgical residency marks the start of a new way of learning. Prior to that time, you may well have invested effort in accumulating knowledge of facts or understanding of concepts that you knew you were extremely unlikely to ever need beyond the next examination. Suddenly, however, as a resident you are placed in a situation where you need to rapidly acquire information that you can use to build a sophisticated understanding of diseases and operations. You have a huge amount to learn and don't have much time to waste on nonproductive educational activities. Much more than ever before, you need to retain the information you have encountered, store that information in ways that allow you to

retrieve it in the future, and relate the information to other pieces of information you have acquired.

How can we describe the transition from the first-year resident with a limited repertoire to the respected senior surgeon? A model that is widely used is the Dreyfus model,¹ originally used to describe the performance progression of U.S. Air Force pilots. The Dreyfus system (Fig. 1.1) specifies five levels of accomplishment: novice, advanced beginner, competent, proficient, and expert.

- 1 A novice is capable of following rules, but not capable of changing the rules to adapt to new circumstances or knowing when the rules don't apply. For example, the novice is capable of generating a standard set of postoperative orders, but would not be able to significantly modify them for individual patients. When the novice sees a patient, he or she has had so little experience that he or she cannot call on mental images of a disease—the novice is forced to depend on analytic reasoning to try to tie the pathophysiology he or she has studied to symptoms and signs. The advanced beginner still functions largely on the basis of rules, but begins to develop some flexibility in applying them. The advanced beginner has had enough clinical experience to begin to recognize patterns in the patients he or she has encountered.

The competent surgeon begins to identify patterns in situations and has started to develop mental models of diseases and operations that guide his or her decision making. To a limited extent, the competent surgeon is able to apply knowledge of the known to new and unknown situations. At this stage, experience begins to supplant rules. The competent surgeon also begins to accept responsibility for the care of the patient and becomes more emotionally involved with patients.

The proficient surgeon is able to effortlessly recognize many situations, drawing on his or her extensive real-world experience and significant prior learning stored in memory. The proficient surgeon may appear to operate from instinct because of the fluidity of his or her decision making, but the "instinct" is derived from a store of experience that has created models that allow the surgeon to choose quickly among competing scenarios.

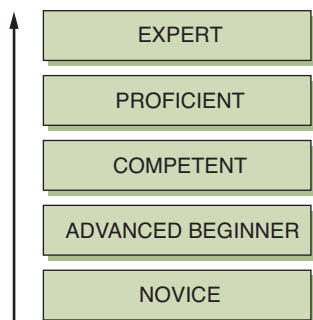

FIGURE 1.1. The Dreyfus model of performance (see also Carraccio C, Benson B, et al. From the educational bench to the clinical bedside: translating the Dreyfus developmental model to the learning of clinical skills. *Acad Med* 2008;83:761–767).

Finally, the expert seems to “always get it right.” The expert routinely comes up with an optimal performance and appears to do it effortlessly. The expert’s mental models of disease are so strong that he or she recognizes atypical features of cases that others miss. The expert may depend so much on “second nature” that he or she actually has difficulty describing his or her decision-making process. In general, the development of expertise in a given area takes 10 years or more. Most experts in surgery have focused on a particular area of surgery for decades.

The Science of Learning and Memory

The activities of your brain are conducted by cells, of which there are approximately 1 trillion. The number of brain cells does not increase during life; rather, the development of the brain results from increasing complex connections made between the brain’s neurons, of which there are about 100 billion, the remainder of the brain cells being glial cells that organize and support the neurons. Neurons communicate with each other via dendrites and axons, the dendrites carrying impulses to the neuron and the axon carrying impulses from the neuron to the dendrites of surrounding neurons. Because an individual neuron can have thousands of dendrites, the number of possible interactions between cells becomes almost unlimited.

Learning occurs when the brain acquires new information; memory is the process through which that information is retained and stored for later retrieval.² When learning occurs, certain neurons start to function together. Repeated activation of those neurons makes subsequent activations faster and in some cases automatic, leading to the creation of memory. Storage of learning in memory in turn activates additional neuronal connections and associations.

Memory appears to be of three types: immediate memory, working memory, and long-term memory. Immediate memory allows you to recall enough information to quickly perform a task such as entering a patient’s name into a computer and spelling it correctly. Working memory confers the ability to process information during the completion of tasks that take minutes to hours. Long-term memory refers to the storage of information for months or years. Storage of this type of information starts with the information being encoded by the hippocampus, which then exports it to long-term storage areas. A very important goal in surgical education is to increase the likelihood that important information will be retained and stored in long-term memory. Two factors that have been shown

to be important in ensuring retention are sense and relevance. Sense implies that the information fits in with the learner’s previous experience. Relevance means that the information is much more likely to be retained if it has meaning for the learner and is related to the learner’s real-life activities. Both of these principles are very important to keep in mind in the training of surgeons. As a resident, trying to read about endocrine surgery may not be very effective in promoting long-term memory if you are in the midst of a demanding vascular surgery rotation and have not had previous exposure to very many patients with endocrine problems.

Learning with Understanding

Learning with understanding occurs when the learner can make sense of new information in light of previous experience and can also see that the information is relevant to his or her learning needs. As one learns with understanding, pieces of information begin to relate to each other and eventually information is clustered in “mental models” or “scripts.” Material that is learned with understanding can not only be recalled but can also be used when novel but related situations are encountered. Recent work suggests that it is the elaborateness and depth of these “illness scripts” that characterize the expert physician.³ Learning with understanding is not easy. As noted previously, learning with understanding can be quite difficult if the learner is not sufficiently familiar with a subject to be well positioned to learn more. Sometimes the prior information that a learner possesses about a subject is incorrect and is difficult to eradicate. In surgery, learning with understanding is complicated when the learner is presented with conflicting information or misinformation from faculty or reading materials.

The remainder of this chapter deals with reading and how one can use a textbook in a way that is most likely to lead to learning with understanding and timely progress toward proficiency or expertise. Surgeons learn in many ways, and some are undoubtedly inclined to rely more on “doing” than reading. Reading is critical to learning to become a surgeon because it is a major way that experts transmit their accumulated understanding to those who are at lower stages in their comprehension. It is very hard to think of another way of learning that does this more efficiently. Having said this, reading is often not done well, not done efficiently, and not done at the right time and place. In the ensuing pages, we hope to offer practical advice about using this textbook and other printed materials to your maximal advantage in your surgical career.

READING FOR RETENTION AND TRANSFER—REMEMBERING FOLLOWS UNDERSTANDING

How do you read a chapter and more easily remember the material? What study strategies enable you to read efficiently, yet also permit you to retrieve the information from memory for use in patient care and on examinations? Why is it that sometimes you are asked a question on a topic about which you remember reading, but your recollection of the details is clouded? These are common concerns expressed by surgeons working to build and maintain a solid knowledge base in an era when the amount of knowledge is doubling every 18 months.⁴ In this portion of the chapter, we will explain approaches individuals may take to learn new information and then describe reading and study activities that promote deep

understanding and help translate new information into retrievable knowledge.

Surface Versus Deep Structured Learning Approaches

The retention of information in long-term memory is affected by a student’s approach to learning. Individuals have tendencies to use either a surface or deep structured approach to reading and studying, although any given individual may change his or her approach at times. Readers who take a surface approach read “on autopilot,” not processing or fully thinking about the information being read. These individuals may go through the motions of highlighting sections in the text, but they don’t carefully choose key points. These learners tend to memorize facts indiscriminately, treat what is being read as unrelated bits of information, and find difficulty in later explaining what they read in their own words.⁵ Surface readers glean satisfaction from the number of pages “covered,” but then have difficulty remembering the content because the words were never translated into personally meaningful information. Surface-level readers search for facts that might appear on the test but not for the meaning of the text. A surface approach leads to temporary and superficial engagement with the educational material and does not promote long-term retention or understanding because little active thinking occurred during reading. A negative association has been reported between the surface study approach and exam performance. This approach is common in learners who are stressed, have performance anxiety, have little interest in the topic, possess limited time management skills and try to read too much in too little time, or lack the ability to discriminate between essential and less important concepts, thereby missing “the forest for the trees” and drowning in information overload.⁶

In contradistinction, deep structured learners are motivated by natural curiosity and a genuine need to know. Their purpose for reading is to acquire information that is considered relevant and personally meaningful. They take control of their own learning and seek to fully understand a topic. They recognize when they understand what is being read, and also recognize when they need more or different information to fully comprehend the material. These learners mentally engage with the information they read by questioning the material, asking themselves about key points, analyzing the material for relationships with what they already know through experience or prior knowledge, and identifying underlying principles to guide their thinking. A deep structured learning approach is an active, integrative process. It results in learners translating the words, charts, and other forms of information into an organized mental picture. This deep and structured approach leads to long-term retention.⁷

Study Considerations and Strategies

Some readers fall asleep while reading, or find themselves having to reread a paragraph several times. Others commit to studying for a block of time, only to start hours later because they found other things to do. Active reading requires a person’s full attention. Even with the best of intentions, a reader’s success can be compromised if concentration is lacking. It is important to minimize or eliminate visual or auditory distractions and to improve the study environment if there is poor lighting, clutter, or uncomfortable seating. Internal distractors (hunger, performance anxiety, sleepiness, etc.) require attention as well. In order to use study time well, keen and consistent concentration are needed.^{8,9}

Table 1.1 demonstrates a three-step reading approach designed to promote deep structured learning.¹⁰ In the first stage, learners prepare before reading by activating their prior knowledge and setting themselves up to read with a purpose. The second stage suggests ways to process the information while reading and make it personally meaningful. The last step reinforces the need to revisit and rehearse what was read to better transfer the information from short-term to long-term memory.

Before Reading: Activate Prior Knowledge

There is a well-established correlation between prior knowledge and reading comprehension.^{11,12} Before reading new material, the learner should carefully reflect on what he or she already knows about the topic and how it relates to other subjects already studied. Prior knowledge is the foundation upon which new information is built. A person with a high level of prior knowledge on a given topic can comprehend what is being read in less time and with less effort than a person who has limited experience or knowledge about the subject. Prior knowledge helps learners construct concepts and make meaning out of what is being read.^{13,14} By activating existing knowledge about a topic before reading more about it, the learner can identify knowledge gaps and then actively read with the clear aim to fill them. Several strategies exist for activating one’s prior knowledge, including reflection and recording, interactive discussions, question and answer development, hypotheses development, and deciding what information about the subject matters the most.

Reflection and Recording. One of the simplest methods is to bring to mind the subject and note what you know about it. You can revisit existing knowledge by listing the chapter headings and subtitles and documenting what you already know. For example, assume that a chapter entitled “Shock” lists eight subtitles: pathophysiology, evaluation of shock, classification of hemorrhage, treatment of hemorrhagic shock, resuscitative fluids, special situations, experimental resuscitative fluids, and complications of shock. The process of briefly recording what

TABLE 1.1

STRATEGIES TO ACHIEVE DEEP STRUCTURED READING

BEFORE READING	DURING READING	AFTER READING
Activate prior knowledge: <ul style="list-style-type: none">■ Reflect and record■ Discuss■ Identify questions■ Make predictions■ Decide what matters most	Take notes: <ul style="list-style-type: none">■ Pictorial: Flow charts, maps, diagrams■ Verbal: Cornell method■ Combined: Virtual Web page design	Rehearse: <ul style="list-style-type: none">■ Periodic reviews■ Self-assessment■ Summarize

you already know about each of these areas stimulates memory, clarifies what is known, and highlights learning gaps or needs. This prepares you to read actively and selectively to fill knowledge voids while also efficiently verifying that your comprehension in areas where you have prior knowledge is sufficient.

Interactive Discussion with Others. Some people activate prior knowledge best through verbal exchange with others. Talking with a colleague about a specific topic can help highlight key points to be studied, highlight lessons learned through personal experiences, and clarify one's understanding about the topic. These discussions can also yield important questions about the topic that require attention as well as provide an organizational structure for thinking about the subject.

Question Development. Generating questions about a topic prior to reading helps you articulate what you think is important to know. It encourages you to think broadly about the subject and anticipate what information might be needed to take care of a patient with the given disease. You might anticipate a question posed by faculty or on an exam, or connect the topic with a patient care problem you've heard about, personally encountered, or anticipate being faced with in the future. When authoring questions on a topic, you should include questions related to word definitions, cause-effect relationships, and comparison-contrast information (how do the symptoms of appendicitis differ from other diseases causing abdominal pain?). The process of asking questions about a topic (I wonder why. . . ; what causes. . . ; how is X similar to Y. . . ; how is it different than Z. . . ; what if the patient is. . .) requires you to think deeply about what you don't understand about the topic so reading can be focused to address identified learning needs. Noting questions before reading and then recording the answers while reading activates preknowledge, links the new information to forethought, and helps translate what is read to real-life situations, which makes the information all the more memorable.

Prediction or Hypothesis Development. Learners benefit from making predictions about various aspects of a topic by tapping into what they already know and predicting how it relates to the subject under study. For example, if reading about rectal cancer, the reader might predict that multimodality therapy is frequently employed, based on his or her preexisting knowledge of pelvic anatomy and lymphatic drainage and past experience with other gastrointestinal malignancies. By hypothesizing answers to key knowledge gaps, readers can test their assumptions through focused reading.

Deciding What Matters Most. Because time for study is limited, it is helpful to pause before reading about a topic to think about which aspects of it are critical, important, or useful to know. Focusing your reading can be done by any of the methods previously mentioned, as well as by simply listing personal learning objectives such as, "By the end of this study period concentrating on benign breast disease, I want to be able to do the following: (a). . . ; (b). . . ." This process activates prior knowledge by determining what components of the topic are most important to you so you can then actively read the chapter with your objectives guiding your study.

During Reading: Taking Notes

If you don't possess a photographic memory or an expert's large store of prior knowledge on a subject so that material being read can be easily organized into long-term memory, note taking is needed or the material will be easily forgotten. It is inefficient to re-read each chapter or even review "highlighted"

paragraphs. Interactive note taking leads to stronger memories and improved concentration while reading. According to Pauk and Owens,¹⁵ note taking focuses attention on what is being read, which strengthens the original memory trace of the material. In addition, it results in a document available for later review and reinforcement. The aim is to create condensed notes driven by the identified learning needs from the "Before Reading" exercises described earlier, formatted for efficient future review and self-testing. Three note-taking methods are described in this section: visual notes, verbal notes, and combined visual/verbal notes.

Visual Notes. Visual notes help learners organize information because they show relationships and hierarchies of concepts. Types of graphic organizers include tables, pictures, flowcharts, mind maps, and diagrams.¹⁶ Graphic organizers are often already published in the text and serve to highlight the importance of the information. Reading the published version, however, is less useful than constructing your own because creating your own version requires more information processing. Nevertheless, it can be useful to copy graphic organizers from a book to carry in a lab coat pocket to review during windows of available time or access when a clinical opportunity arises. Another strategy is to omit the data in parts of the published graph and later "fill in the blanks" to further reinforce understanding and retention.

Tables are useful for comparing and contrasting common types of details across variables. For example, a table would be helpful to learn about the various imaging techniques for pancreatic cancer. The column headings might include "Name of Test," "Cost," "Risks," "Sensitivity," "Specificity," and "Positive Predictive Value." This approach allows you to extract information from the book's narrative and place it in the correct location in the table format. The finished table enables you to compare and contrast the tests and create a "big picture" view of the multiple factors involved in choosing an optimal diagnostic tool.

A flowchart is a picture of the separate steps of a process in sequential order. Translating the material you read into a flowchart helps you think through "if-then" scenarios and can uncover your incorrect or unclear decision pathways. After reading a segment of a chapter on a particular disease entity, you can, for example, draw a scheme for working up a jaundiced patient or create an algorithm for the treatment of pulmonary embolus.

Mind maps, sometimes referred to as concept maps, relate facts or ideas to other facts or ideas. Relationships and patterns across information are easily seen in mind maps. A mind map is a structured graphic display of an individual's conceptual scheme within a well-circumscribed domain.^{17,18} There are various approaches to developing mind maps, but most methods share similar steps. The first step, the brainstorming stage, occurs by drawing or writing the topic in the center of the page (Fig. 1.2). If the chapter under study is about gastroesophageal reflux disease (GERD), the reader would write the word "GERD" in the middle of a large sheet of blank paper. Lines are then drawn from the center topic outwardly to represent the main ideas or categories that are written or illustrated in the reading. Subheadings from the book could be used for these "spokes," or the reader can choose his or her own collection of key ideas. For example, one spoke might have printed on it "Diagnosis" and a second spoke may contain the word "Treatment." A third spoke might be "Epidemiology," and a fourth might read "Complications." Given that our minds don't think in a linear fashion, mind or concept maps enable readers to build branches and subbranches onto the main spokes or build more main spokes, depending on what they are thinking at the time. Any number of branches can be added to the major spoke lines. Learners continue to build their maps as their thoughts and "search and find" mental association powers are

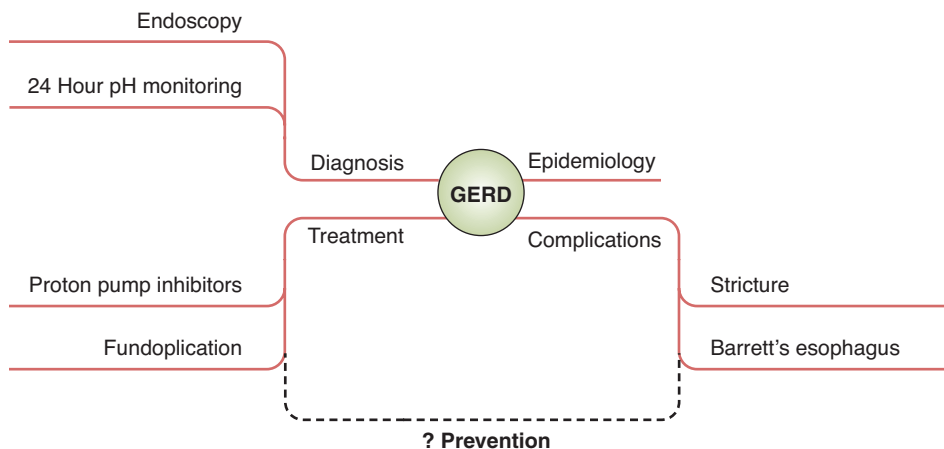

FIGURE 1.2. A basic “mind map” dealing with the topic of gastroesophageal reflux.

unleashed. Mapping allows for free-flow thinking and spontaneous thought and decreases the chances of premature closure about a topic or subtopic, which typically happens when using an outline approach.

Once the initial brainstorming map is completed, the “organizational stage” needs to occur. In this phase, readers redo their mind maps, sequencing the branches in sort of meaningful order. During this phase, readers may see hierarchies or new associations that can serve as a basis for organizing or modifying the map’s branches or subbranches. Additional details on how to construct mind maps are published elsewhere.¹⁹

Other types of graphic organizers include diagrams or pictures. The latter can be helpful, for example, in summarizing a segment of a chapter that describes anatomy. Anatomic pictures can either be drawn or copied from the Internet or other printed source and used to note structures. Creating graphics helps readers activate background knowledge, strengthens metacognitive skills, strengthens their ability to construct meaning from the printed word, and reinforces understanding.

Verbal Notes. Research suggests that underlining (or highlighting) while reading leads to greater understanding than reading alone, but writing notes while reading is significantly better for retention than underlining. Creating summaries in your own words of the material you read is critical to converting learning into memory. If notes can’t be done easily, then the information is not well enough understood to be incorporated for the long term. One note-making system worth considering is the Cornell method.¹⁵ This method, pictured in Figure 1.3, provides a format for condensing and organizing notes. It makes use of paper with a 2.5-inch margin on the left and a 6-inch area on the right in which to write notes. While reading, you write cue words in the left margin and key phrases or points in the right. Later, when reviewing notes, you can view the cue word while simultaneously covering up the key phrases to discern whether you can extemporaneously come up with the key points. For example, while studying the principles of tumor biology, cue words in the left margin might read “how cancers develop,” “role of the host,” “clinical staging,” etc. The bottom 2 inches of the page are used to write summary information or to note areas that need additional study. Templates for the Cornell method note formats and instructions about how to use them can be found on the Internet.

Combined Methods. There are many ways you can interact with the material you read, be it verbally or visually. With today’s technology, you could set up a Web page for your reading notes. The Web page could include visual and verbal notes, all organized using a structure that makes sense to you.

After Reading: Rehearse

The importance of reviewing and rehearsing notes cannot be overemphasized in terms of its importance to long-term memory. Rehearsing material repeatedly helps it become “overlearned” and thus embedded in your memory. The passage of time can be detrimental to memory, but returning to review notes at the start of each study session can significantly increase retention. There is consistent evidence that the process of rehearsal and recitation transfers information from short-term memory into long-term memory.²⁰ Recitation or rehearsal can include reflecting on the topic, writing about it, answering the questions you posed at the prereading stage, and/or talking to yourself or others about it. It is best to write or talk aloud when rehearsing because it involves multiple senses, which increases the chances of remembering the material. Consider reviewing by offering to teach the topic to others—“to teach is to learn twice.” When reviewing information, you will be more successful if your notes are

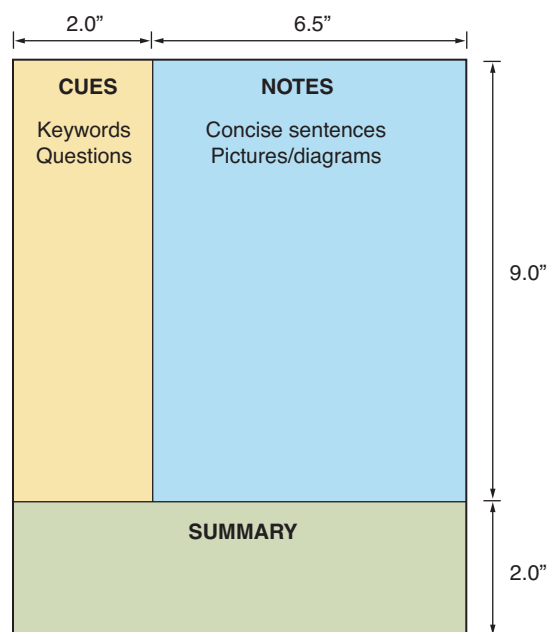

FIGURE 1.3. The Cornell method for note taking (see also Pauk W, Owens R. *How to Study in College*, 8th ed. Boston, MA: Houghton Mifflin Company Publishers; 2005).

organized in a manner that supports a systematic search, such as by hierarchies or categories. The rehearsal process requires processing the information by analyzing it, not merely reciting it.

Self-assessment is a helpful form of rehearsal. Multiple-choice practice exams are convenient, but open-ended questions allow for a richer interaction with the material and avoid some of the artifact in multiple-choice questions that is introduced by distractors. In summary, rehearsal is a critical part of learning. Periodic and consistent review will help you refresh and build your memory.

MONITORING YOUR LEVEL OF READING COMPREHENSION

Early in your education, your teachers helped you develop strategies to assess and improve reading comprehension. These strategies, known as *comprehension monitoring*, are likely so engrained in your reading process that now you give little thought to them.

- 4 Comprehension strategies are “specific, learned procedures that foster active, competent, self-regulated, and intentional reading.”²¹ The number and type of comprehension monitoring strategies that you use is predictive of retention.²² Therefore, it is recommended that you do a personal inventory of your strategies before embarking on the difficult task of reading a surgery textbook to ensure that you are using your reading time as effectively as possible (Table 1.2).

Your goals for text comprehension should be related to your desired outcome. If you are reading to learn and remember the factual answers to questions you anticipate will be asked of you during an upcoming conference, your strategies may be confined to recitation or listing. If your goal is to understand how or why a patient responds to a particular drug, your need for deeper processing requires that you use more elaborate comprehension monitoring strategies such as schematic mapping or written summaries. Studying for a high-stakes examination, such as the American Board of Surgery Qualifying or Certifying Examination, requires more elaborate comprehension strategies aimed at deeper processing.

TABLE 1.2

SUMMARY OF POSSIBLE STRATEGIES FOR MAXIMIZING READING COMPREHENSION

- Select reading materials of appropriate difficulty, suitable for academic progress and purpose
- Identify sources of potential personal bias or error in judging reading comprehension
- Do massed re-reading to improve fluency and/or immediate recall
- Use deep structured reading approach to improve understanding and retention
- Discuss reading content with colleagues to gauge your level of understanding
- Use self-assessments such as review guides or question banks
 - Select self-assessment materials that are similar in format and difficulty to your targeted purpose for reading
 - During self-assessments, stop and reflect on justifications for answering questions

Comprehension monitoring is a metacognitive activity that includes self-evaluation and self-regulation. *Self-evaluation* refers to whether or not you understand what you have read. *Self-regulation* is the act of taking steps to correct problems you detect during self-evaluation. Of importance in this process is a sincere attempt to judge future performance—in other words, “do I understand this well enough now to do well on a future test? Or make a diagnosis in a patient?” The judgments you make about future performance impact what and how much you study, so honest and accurate self-assessment is important.

Being familiar with one’s own limitations about knowledge, memory, and performance under stress is critical for enhancing accurate judgments about future comprehension performance. Accurate predictions require perspective, a capacity for self-criticism, and an understanding and acceptance of biases that lead to cognitive error.^{23,24} Cognitive dispositions to respond (CDRs) to situations in predictable ways can lead to errors in critical thinking. An example of a CDR that can lead to cognitive error is “search satisfying,” which occurs when a search is called off once something suitable is found. In diagnosing a source of pain, for example, a plausible explanation is encountered, causing you to cease the search for others. Awareness of these pitfalls and using a strategy for reducing cognitive error (continuing your search for other potential causes of pain) are known as cognitive forcing strategies. Getting perspective and reflecting on one’s thinking process during reading, or in clinical situations, is an effective means for avoiding or minimizing potential errors in critical thinking.²³

The judgments you make about reading comprehension are limited by the subjectivity inherent to self-evaluation.²⁵ The more familiar you are with a topic, the more likely you will overestimate your comprehension of it.²⁶ While we recommend that you read about topics related to your current rotation and patient encounters in order to take advantage of the retention effect of activating prior knowledge, be aware that when you are reading about a topic of immediate familiarity, you may overestimate your understanding of the material. Using a range of evaluation strategies to monitor your comprehension can help to avoid misinterpreting familiarity as understanding.

The more coherent or easier textual material is to process, the higher you will judge your comprehension to be.²⁶ Reading texts and review guides that provide abbreviated overviews of surgical topics may be an expeditious way to cover a topic. However, the easier-to-process text may give you the misimpression that you comprehend more than you actually do about the subject you are reading.

Massed re-reading, or reading text twice in a row, has been shown to improve memory of information in the text on free recall and also improve the accuracy of comprehension monitoring.²⁷ However, recent studies of massed re-reading compared to single reading demonstrate that massed re-reading is not an effective means of improving performance on multiple-choice tests.²⁸ Re-reading may be valuable when content is not familiar. However, the fluency gained during a re-read can be misunderstood as improved comprehension when, in fact, massed re-reading alone does not typically result in the deeper processing necessary for the level of comprehension that leads to retention.

Comprehension accuracy can be improved by reducing uncertainty about the context in which you will need to recall information.²⁶ Familiarizing yourself with the examination format and with the type of information that will be targeted in the test can improve your judgment about your readiness. Another recommendation for improving accuracy of judgments about comprehension involves using colleagues to anchor your judgments. Reducing the subjectivity inherent in self-evaluation can be accomplished by talking with others about the text after reading it.

Using your performance results from previous exams can serve as an effective guide for reading goals. A review book that mirrors the complexity of the questions you will face on an exam can also help reduce the uncertainty you may have about your future comprehension performance. Using a good review guide or question bank in conjunction with your textbook reading can both help you become familiar with test format and assess your retention. While taking practice tests, stop at intervals to review your answers (e.g., every 10 questions) and consider your justification for the responses you gave. This type of self-assessment has been shown to improve future test performance, a result attributed to the critical thinking or reasoning required by the process.²⁹ Rephrasing and justification about reasoning are also metacognitive strategies that can improve retention and future comprehension performance.

CHAPTER 2 ■ SUBSTRATE METABOLISM IN SURGERY

STEVEN E. RAPER

KEY POINTS

- 1 Intermediary metabolism—as the metabolic manipulation and balancing of ingested carbohydrate, fat, and protein—ultimately can process all nutrients to acetyl coenzyme A (CoA) for energy production in the citric acid cycle.
- 2 Glucose must always be available for brain function; if not available directly from the diet, it can be mobilized for a brief period from glycogen stores and then derived from proteins in the liver and kidneys.
- 3 Free fatty acids are a direct source of energy catabolized by cardiac and skeletal muscle.
- 4 Hepatic protein synthesis, when excess amino acids are available, includes albumin, fibrinogen, and apolipoproteins and can reach 50 g per day.
- 5 The citric acid cycle includes a series of mitochondrial enzymes that transform acetyl CoA into water, carbon dioxide, and hydrogen-reducing equivalents; the hydrogen-reducing equivalents are then transformed into adenosine triphosphate (ATP) by the electron transport chain. Each molecule of acetyl CoA that enters the citric acid cycle yields 12 molecules of ATP.
- 6 Biotransformation of potentially toxic, often hydrophobic, compounds into hydrophilic, excretable compounds occurs mainly in the liver by the cytochromes P-450, the uridine diphosphate-glucuronyl (UDP-glucuronyl) transferases, the glutathione (GSH) S-transferases, and the sulfotransferases.

INTERMEDIARY METABOLISM: AN OVERVIEW

“[D]o You Have a More Exciting Word for ‘Metabolism’?”*

Intermediary metabolism is the fate of dietary carbohydrate, fat, and protein after digestion and absorption. Although admittedly intricate, all surgeons should be familiar with the chemical reactions by which food is converted to energy. Understanding the major biochemical pathways is a prerequisite to making use of the rapid—and exciting—expansion of medical knowledge directed at improving health beginning at the cellular level. Some representative recent advances will be discussed at the end of the chapter.

1 The major intermediary metabolites are glucose, fatty acids, glycerol, and amino acids. Glucose is metabolized to pyruvate and lactate by glycolysis. Aerobic metabolism allows conversion of pyruvate to acetyl coenzyme A (CoA). Acetyl CoA enters the citric acid cycle resulting in carbon dioxide, water, and reducing equivalents (a major source of adenosine triphosphate [ATP]). In the absence of oxygen, glycolysis ends in lactate. Glucose can be stored as or created from glycogen. Glucose can also enter the phosphogluconate pathway, where it is converted to reducing equivalents for fatty acid synthesis and ribose five-carbon sugars important in nucleotide formation. Glucose can be converted into glycerol for fat formation and pyruvate for amino acid synthesis. Gluconeogenesis allows synthesis of glucose from lactate, amino acids, and glycerol.

With regard to lipid metabolism, long-chain fatty acids arise from dietary fat or synthesis from acetyl CoA. Fatty acids can be oxidized to acetyl CoA by the process of β -oxidation or converted to acyl glycerols (fat) for storage as the main energy reserve. In addition to the fats noted previously, acetyl CoA can be used as a precursor to cholesterol and other steroids and in the liver can form the ketone bodies acetoacetate and 3-hydroxybutyrate, which are critical sources of energy during periods of starvation.

Proteins are degraded in two major ways: energy independent, usually in lysosomes, and energy requiring, usually through the ubiquitin pathway. Of amino acids generated in protein catabolism, about three fourths are reutilized for protein synthesis and one fourth are deaminated, with the resulting ammonia converted to urea. Amino acids may be divided into nutritionally essential and nonessential. Nonessential amino acids require fewer enzymatic reactions from amphibolic intermediates or essential amino acids. Each day, humans turn over 1% to 2% of total body protein.

CARBOHYDRATE METABOLISM

The products of intestinal carbohydrate digestion are glucose (80%) and fructose and galactose (20%). Fructose and galactose are rapidly converted to glucose, and the body uses glucose as the primary molecule for transport and uptake of carbohydrates by cells throughout the body. Blood glucose levels are tightly regulated by the liver despite wide fluctuations in dietary intake. About 90% of portal venous glucose is removed from the blood by liver cells through carrier-facilitated diffusion. Large numbers of carrier molecules on the sinusoidal domain of the hepatocyte are capable of binding glu-

cose and transferring it to the cytoplasm. The rate of glucose transport is enhanced (up to 10-fold) by insulin. Given the critical role of glucose in survival, complex metabolic pathways have evolved for the storage of glucose in the fed state, the release of glucose from glycogen, and the synthesis of new glucose.

Blood glucose is stored, primarily in liver and muscle, as glycogen. Glycogen is a complex polymer of glucose with an average molecular weight of 5 million. The liver can convert up to 100 g of glucose into glycogen per day by glycogenesis. The liver can also release glucose into the blood by glycogenolysis, which is the breakdown of glycogen, or by gluconeogenesis, which is the formation of new glucose from substrates such as alanine, lactate, or glycerol. Hormones play a key role in the hepatic regulation of glycogen balance. Insulin, for example, stimulates glycogenesis and glycolysis; glucagon stimulates glycogenolysis and gluconeogenesis.¹

Glycogenesis and Glycogenolysis

The first step in glycogen storage is the transport of glucose through the plasma membrane. Once in the hepatocyte, glucose and ATP are converted by the enzyme glucokinase to glucose-6-phosphate (G6P), the first intermediate in the synthesis of glycogen (Fig. 2.1). Because complete oxidation of one molecule of G6P generates 37 molecules of ATP, and storage uses only one molecule of ATP, the overall efficiency of glucose storage as glycogen is a remarkable 97%. Glycogenolysis does not occur by simple reversal of glycogenesis. Each succeeding glucose on a glycogen chain is released by glycogen phosphorylase (Fig. 2.2). Eventually, G6P is re-formed. G6P cannot exit from cells and must first be converted back to glucose. The conversion of G6P to glucose is catalyzed by glucose-6-phosphatase, which exists only in hepatocytes, kidney, and intestinal epithelial cells. **2** Neither brain nor muscle cells, which use glucose as a primary fuel source, contain the phosphatase enzyme. This lack of glucose-6-phosphatase ensures a ready supply of glucose for the energy needs of brain and muscle. Liver does not use glucose primarily for fuel but as a precursor for other molecules.

FIGURE 2.1. The chemical reactions of glycogenesis and glycogenolysis. Glucose-6-phosphatase allows hepatic glucose to be transported out of the hepatocyte for use in other tissues. Glucose-6-phosphate, in red, plays a central role in carbohydrate metabolism.

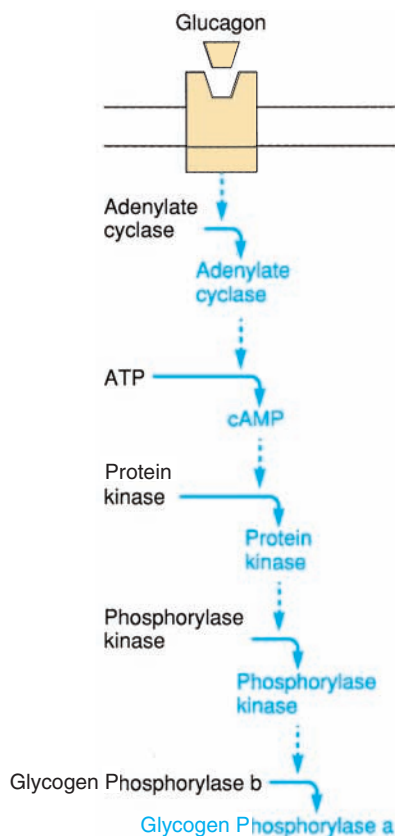

FIGURE 2.2. Glucagon-stimulated enzyme cascade, responsible for the control of glycogen metabolism. Inactive forms are shown in black, active forms in blue.

Glycolysis

Glycolysis is the pathway—in all mammalian cells—by which glucose is converted to pyruvate or lactate (Fig. 2.3). The glycolytic pathway is interesting in that glucose can be metabolized in the presence (aerobic) or absence (anaerobic) of oxygen. The aerobic conversion of glucose to pyruvate has three effects: (a) a net gain of two ATP molecules, (b) generation of two reducing equivalents of the nicotinamide adenine nucleotide ($\text{NADH} + \text{H}^+$), or (c) conversion of pyruvate to acetyl CoA with subsequent degradation of acetyl CoA in the citric acid cycle (see later). The conversion of glucose to pyruvate is regulated by three enzymes: hexokinase (glucokinase), phosphofructokinase, and pyruvate kinase, which are non-equilibrium reactions and as such, functionally irreversible.

Under anaerobic conditions, $\text{NADH} + \text{H}^+$ cannot be reoxidized by transfer of reducing equivalents through the electron transport chain to oxygen. Instead, pyruvate is reduced by the $\text{NADH} + \text{H}^+$ to lactate. Glycolysis takes place in the cytoplasm, in contrast to the citric acid cycle, which is a mitochondrial process. During times of glucose excess, as in the fed state, hepatic glycolysis can generate energy in the form of ATP, but the oxidation of ketoacids is a preferred hepatic energy source.

In erythrocytes, a unique variant of glycolysis enhances oxyhemoglobin dissociation. The first site in glycolysis for generation of ATP is bypassed, leading to the formation of 2,3-bisphosphoglycerate by an additional enzyme called bisphosphoglycerate mutase. Kinetics of the mutase present in erythrocytes allow the presence of high concentrations of

FIGURE 2.3. The glycolytic pathway. There is a net gain of two adenosine triphosphate molecules per glucose molecule. Phosphofructokinase is the key regulatory enzyme in this pathway; however, all the enzymes in red catalyze irreversible reactions. The pathway shown here is active only in the presence of aerobic conditions.

2,3-bisphosphoglycerate to build up. The 2,3-bisphosphoglycerate displaces oxygen from hemoglobin, allowing a shift of the oxyhemoglobin dissociation curve to the right.

Gluconeogenesis

There is an absolute minimum requirement for glucose in humans. Below a certain blood glucose concentration, brain dysfunction causes coma and death. When glucose becomes scarce, as in the fasting state, glycogenolysis occurs. Once glycogen stores have been depleted, the liver and kidneys are capable of synthesizing new glucose by the process of gluconeogenesis. Glucagon is produced in response to low blood sugar levels and stimulates gluconeogenesis. Gluconeogenesis is not a simple reversal of the glycolytic pathway. In glycolysis, as noted previously, the conversion of glucose to pyruvate is a one-way reaction. As a result, four separate, functionally irreversible enzyme reactions are required to convert pyruvate into glucose (Fig. 2.4). These enzymes are pyruvate carboxylase,

FIGURE 2.4. The gluconeogenesis pathway. The irreversible nature of the glycolytic pathway means that a different sequence of biosyntheses is required for glucose production. The enzymes in red catalyze irreversible reactions that are different from those in glycolysis. In mammals, glucose cannot be synthesized from acetyl coenzyme A, only from cytosolic pyruvate.

phosphoenolpyruvate carboxykinase, fructose-1,6-bisphosphatase, and glucose-6-phosphatase. Other enzymes are shared with the glycolytic pathway.

About 60% of the naturally occurring amino acids, glyceral, or lactate can also be used as substrates for glucose production. Alanine is the amino acid most easily converted into glucose. Simple deamination allows conversion to pyruvate, which is subsequently converted to glucose. Other amino acids can be converted into three-, four-, or five-carbon sugars and then enter the phosphogluconate pathway (see later). Gluconeogenesis is enhanced by fasting, critical illness, and periods of anaerobic metabolism. Active skeletal muscle and erythrocytes form large quantities of lactate. In patients with large wounds, lactate also accumulates. The conversion of lactate

FIGURE 2.5. The Cori cycle, an elegant mechanism for the hepatic conversion of muscle lactate into new glucose. Pyruvate plays a key role in this process.

(through pyruvate) to glucose—a process possible only in the presence of oxygen—is an important means of preventing severe lactic acidosis (Fig. 2.5).

Phosphogluconate Pathway

When glucose enters the liver, glycogen is formed until the hepatic glycogen capacity is reached (about 100 g). If excess glucose is still available, the liver converts it to fat by the phosphogluconate pathway (also known as the pentose phosphate pathway) (Fig. 2.6). The cytosolic phosphogluconate pathway

FIGURE 2.6. The phosphogluconate pathway. One of the major purposes of this pathway is to generate reduced nicotinamide adenine dinucleotide, which can serve as an electron donor and allow the liver to perform reductive biosynthesis.

can completely oxidize glucose, generating CO_2 and nicotinamide adenine dinucleotide phosphate (NADPH) through what is known as the oxidative phase. Hydrogen atoms released in the phosphogluconate pathway combine with oxidized nicotinamide adenine dinucleotide phosphate (NADP^+) to form reduced nicotinamide adenine dinucleotide phosphate ($\text{NADPH} + \text{H}^+$).² The oxidative phase is present only in tissues, such as the adrenal glands and gonads, that require reductive biosyntheses such as steroidogenesis or other forms of lipid synthesis. Essentially, all tissues contain the nonoxidative phase, which is reversible and produces ribose precursors for nucleotide synthesis. In erythrocytes, the phosphogluconate pathway provides reducing equivalents for the production of reduced glutathione by glutathione reductase. Reduced glutathione can remove hydrogen peroxide, which increases the conversion of oxyhemoglobin to methemoglobin and subsequent hemolysis.

LIPID METABOLISM

Lipid Transport

Lipid transport throughout the body is made complicated by the fact that lipids are insoluble in water. To overcome this physicochemical incompatibility, dietary triglycerides are first split into monoglycerides and fatty acids by the action of intestinal lipases. After absorption into the small intestinal cells, triacylglycerols are re-formed and aggregate into chylomicrons, which then enter the bloodstream by way of the lymph. Chylomicrons are removed from the blood by the liver and adipose tissue. The capillary surface of the liver contains large amounts of lipoprotein lipase, which hydrolyzes triglycerides into fatty acids and glycerol. The fatty acids freely diffuse into the hepatocytes for further metabolism. Similar to chylomicrons, very low-density lipoproteins (VLDLs) are synthesized by the liver and are the main vehicle for transport of triacylglycerols to extrahepatic tissues. The intestines and liver are the only two tissues capable of secreting lipid particles. In addition to chylomicrons and VLDLs, there are two other major groups of plasma lipoproteins: low-density lipoproteins (LDLs) and high-density lipoproteins (HDLs). LDLs and HDLs contain predominantly cholesterol and phospholipid.

The structure of all classes of lipoproteins is similar. There is a core of nonpolar lipids, either triacylglycerols or cholesterol esters, depending on the particular lipoprotein. This nonpolar core is coated with a surface layer of amphipathic phospholipid or cholesterol oriented so that the polar ends are in contact with the plasma. A protein component is also present. The A apolipoproteins occur in chylomicrons and HDLs. The B apolipoproteins come in two forms: B-100 is the predominant apolipoprotein of LDLs, whereas the shorter B-48 is located in chylomicrons. The C apolipoproteins can transfer between VLDLs, LDLs, and HDLs. Apolipoprotein D and E also exist. Apolipoproteins have several functions in lipid transport and storage. Some, such as the B apolipoproteins, are an integral part of the lipoprotein structure. Other apolipoproteins are enzyme cofactors, such as C-II for lipoprotein lipase. Lastly, the apolipoproteins act as ligands for cell surface receptors. As an example, both B-100 and E serve as ligands for the LDL receptor.^{3,4}

Fatty Acid Metabolism

Most human fatty acids in plasma are long-chain acids (C-16 to C-20). Because long-chain fatty acids are not readily absorbed by the intestinal mucosa, they must first be incorporated into chylomicrons. In contrast, short-chain and medium-chain fatty acids

are absorbed directly into the portal circulation and are avidly taken up by the liver. Free fatty acids in the circulation are non-covalently bound to albumin and are transferred to the hepatocyte cytosol by way of fatty acid-binding proteins. Fatty acid CoA esters are synthesized in the cytosol after hepatic uptake of fatty acids. These fatty acid CoA esters can be converted into triglyceride, transported into mitochondria for the production of acetyl CoA and reducing equivalents, or stored in the liver as triglycerides. The rate-limiting step in the synthesis of triglyceride is the conversion of acetyl CoA to malonyl CoA. Malonyl CoA, in turn, inhibits the mitochondrial uptake of fatty acid CoA ester, favoring triglyceride synthesis. The liver also contains dehydrogenases that can unsaturate essential dietary fatty acids. Structural elements of all tissues contain significant amounts of unsaturated fats, and the liver is responsible for the production of these unsaturated fatty acids. As another example, dietary linoleic acid is elongated and dehydrogenated to the prostaglandin precursor arachidonic acid.

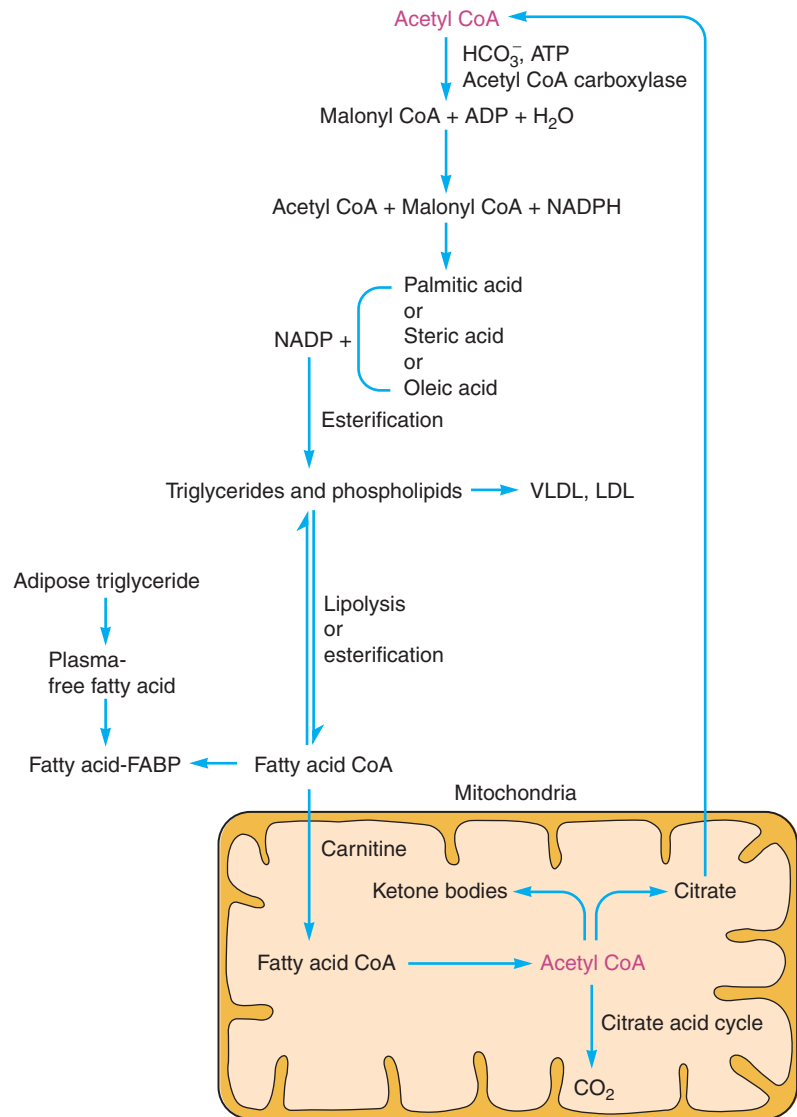

3 Under basal conditions, most free fatty acids are catabolized for energy by cardiac and skeletal muscle. Under conditions of adipocyte lipolysis, the liver can take up and metabolize fatty acids. Although fatty acid synthesis occurs in the cytosol, fatty acid oxidation occurs in the mitochondria. Fatty acid CoA esters bind carnitine, a carrier molecule, and in the absence of cytosolic malonyl CoA, they enter the mitochondria, where they undergo β -oxidation to acetyl CoA and reducing equivalents (Fig. 2.7). Acetyl CoA can then take one of the following routes: (a) enter the tricarboxylic acid cycle and be degraded to carbon dioxide, (b) be converted to citrate for fatty acid synthesis, or (c) be converted into 3-hydroxy-3-methylglutaryl CoA (HMG-CoA), a precursor of cholesterol and ketone bodies. The mitochondrial hydrolysis of fatty acids is a source of large quantities of ATP. The conversion of stearic acid to carbon dioxide and water, for instance, generates 136 molecules of ATP and demonstrates the highly efficient storage of energy as fat. By a process called β -oxidation, acetyl CoA molecules are cleaved from fatty acids. The acetyl CoA is then metabolized through the citric acid cycle under normal circumstances.

In times of unrestrained lipolysis, such as starvation, uncontrolled diabetes, or other conditions of triglyceride mobilization from adipocyte stores, ketone bodies—predominantly 3-hydroxybutyrate and acetoacetate—are formed in hepatic mitochondria from free fatty acids and are a source of energy for extrahepatic tissues. Ketogenesis is regulated predominantly by the rate of mobilization of free fatty acids. Once in the liver mitochondria, the relative proportion of acyl CoA destined to undergo β -oxidation is limited by the activity of an enzyme, carnitine palmitoyltransferase-1. Lastly, there are mechanisms that keep the levels of acetyl CoA entering the citric acid cycle constant, so that only at high mitochondrial levels will acetyl CoA be converted to ketone bodies. Even the brain, in times of starvation, can use ketone bodies for half of its energy requirements. At some point, however, the ability of liver to perform β -oxidation may be inadequate. Under such circumstances, hepatic storage of triglyceride or fatty infiltration of the liver can be significant, leading to the development of nonalcoholic steatohepatitis (NASH). Triglyceride storage by itself does not appear to be a cause of hepatic fibrosis, but fatty infiltration may be a marker for the derangement of normal processes by alcohol or drug toxicity, diabetes, or long-term total parenteral nutrition. A specific type of microvesicular fatty accumulation is also seen in a variety of diseases, such as Reye syndrome, morbid obesity, and acute fatty liver of pregnancy.

Cholesterol Metabolism

Cholesterol is an important regulator of membrane fluidity and is a substrate for bile acid and steroid hormone synthesis.

FIGURE 2.7. Diagram of hepatic fatty acid metabolism. Both dietary and newly synthesized fatty acids are esterified and subsequently degraded in the mitochondria for energy, first as reducing equivalents, then adenosine triphosphate via the electron transport chain.

Cholesterol may be available by dietary intake or by de novo synthesis. In mammals, most new cholesterol is synthesized in the liver from its precursor, acetyl CoA. Dietary cholesterol intake can suppress endogenous synthesis by inhibiting the rate-limiting enzyme in the cholesterol biosynthetic pathway, HMG-CoA reductase. A competitive antagonist, lovastatin, can also block HMG-CoA reductase and effectively lower plasma cholesterol by blocking cholesterol synthesis, stimulating LDL receptor synthesis, and allowing an increased hepatic uptake and metabolism of cholesterol-rich LDL lipoproteins. The structure of the LDL receptor is known and serves as a model for the structure and function of other cell membrane receptors (Fig. 2.8).

Cholesterol is lipophilic and hydrophobic, and most plasma cholesterol is in lipoproteins esterified with oleic or palmitic acid. The liver can process cholesterol esters from all classes of lipoproteins. Hepatocytes can also take up chylomicron remnants containing dietary cholesterol esters. Newly synthesized hepatic cholesterol is used primarily to synthesize bile acids for further intestinal absorption of dietary fats. A large proportion of the bile acids secreted by the liver into bile are returned to the liver via the enterohepatic circulation

(Fig. 2.9). Abnormally elevated levels of cholesterol in VLDLs or LDLs are associated with atherosclerosis, whereas HDL levels are protective.

Phospholipids

The three major classes of phospholipids synthesized by the liver are lecithins, cephalins, and sphingomyelins. Although most cells in the body are capable of some phospholipid synthesis, the liver produces 90%. Phospholipid formation is controlled by the overall rate of fat metabolism and by the availability of choline and inositol. The main role of phospholipids of all types is to form plasma and organelle membranes. The amphiphilic nature of phospholipids makes them essential for reducing surface tension between membranes and surrounding fluids. Phosphatidylcholine, one of the lecithins, is the major biliary phospholipid and is important in promoting the secretion of free cholesterol into bile. Thromboplastin, one of the cephalins, is needed to initiate the clotting cascade. The sphingomyelins are necessary for the formation of the myelin nerve sheath.

FIGURE 2.8. The low-density lipoprotein (LDL) receptor, an example of a transmembrane receptor that participates in receptor-mediated endocytosis. The LDL receptor specifically binds lipoproteins that contain apolipoprotein B-100 or E. Once internalized, the lipoproteins are degraded. AA, amino acids.

PROTEIN METABOLISM

Formation and Catabolism of Plasma Proteins

- 4 Essentially, all albumin, fibrinogen, and apolipoproteins are derived from the liver, which can add up to 50 g of protein to the plasma per day. Of the total hepatic protein synthesized,

75% is destined for export in plasma. Most newly synthesized proteins are not stored in the liver, and the rate of protein synthesis is primarily determined by the intracellular levels of amino acids. The tertiary structure of many proteins undergoes posttranslational modification after they have been synthesized in the liver's rough endoplasmic reticulum (ER). Glycosylation, or the addition of carbohydrate moieties, occurs in the smooth ER. Sialation, or the addition of sialic acid, occurs in the Golgi. Glycosylation is important in allowing some proteins to bind with specific receptors for subsequent hepatic uptake and processing. Removal of sialic acid residues, or desialation, from the terminal galactose molecules of glycoproteins allows them to bind to the asialoglycoprotein (ASGP) receptor in the liver and undergo degradation. Desialation, therefore, is important in the clearance of senescent proteins from the plasma.

Intracellular proteases hydrolyze proteins into peptides, and the peptides are in turn hydrolyzed by peptidases. Ultimately, free amino acids are generated. Unlike carbohydrate and lipids, excess amino acids are degraded if they are not immediately reincorporated into new proteins. Protein degradation occurs primarily by one of two routes. Asialoglycoproteins are internalized into lysosomes via receptor-mediated endocytosis. The lysosomal enzymes do not require ATP and are nonselective in their activities; more than 20 known hydrolytic enzymes are present in lysosomes. A second pathway involves the covalent attachment of ubiquitin, named for the fact that it exists in all mammalian cells, targeting proteins for destruction. This pathway is ATP dependent and generally is used for proteins with shorter half-lives.⁵

Amino Acid Synthesis

Essentially, all the end products of dietary protein digestion are amino acids, which are absorbed by the enterocytes into the portal circulation in an ionized state. Liver amino acid uptake occurs by one of several active transport mechanisms. Amino acids are not stored in the liver but are rapidly used in the production of plasma proteins, purines, heme proteins, and hormones. Under certain conditions, the amine group is removed from amino acids, and the carbon chain is used for carbohydrate, lipid, or nonessential amino acid synthesis.⁶

Ten nutritionally essential amino acids must be obtained from dietary intake (Table 2.1). However, human tissues contain transferases, which convert the α -keto acids of leucine, valine, and isoleucine so that the corresponding α -keto acids can be used as dietary supplements. The remaining nutritionally nonessential amino acids can be synthesized in one to three enzyme-catalyzed reactions. Hydroxyproline and hydroxylysine do not have a corresponding tRNA and arise by post-translational modification of proline or lysine by mixed

FIGURE 2.9. The enterohepatic circulation of bile acids. The primary bile acids, cholic acid and chenodeoxycholic acid, are synthesized in the liver from cholesterol. Deoxycholic acid and lithocholic acid are formed in the colon (blue lines) during bacterial degradation of the primary bile acids. All four bile acids are conjugated with glycine or taurine in the liver. Most of the lithocholic acid is also sulfated, which decreases reabsorption and increases fecal excretion. Bile acids are absorbed passively in the epithelium of the small and large intestine and actively in the distal ileum.

TABLE 2.1

CLASSIFICATION

AMINO ACIDS REQUIRED BY ADULT HUMANS

■ NUTRITIONALLY ESSENTIAL	■ NUTRITIONALLY NONESSENTIAL	
	■ AMINO ACID	■ PRECURSOR
Arginine	Alanine	Pyruvate
Histidine	Asparagine	Oxaloacetate
Isoleucine	Aspartate	Oxaloacetate
Leucine	Cysteine	Methionine
Lysine	Glutamate	α -Ketoglutarate
Methionine	Glutamine	α -Ketoglutarate
Phenylalanine	Glycine	3-Phosphoglycerate
Threonine	Hydroxyproline	α -Ketoglutarate
Tryptophan	Hydroxylysine	Lysine
Valine	Proline	α -Ketoglutarate
	Serine	3-Phosphoglycerate
	Tyrosine	Phenylalanine

function oxidases. Glutamate, glutamine, and proline are derived from the citric acid cycle intermediate α -ketoglutarate. Aspartate and asparagine are synthesized from oxaloacetate. Serine and glycine are synthesized from the glycolysis intermediate 3-phosphoglycerate. Cysteine and tyrosine are formed from essential amino acids (methionine and phenylalanine, respectively).⁷

Catabolism of Amino Acid Nitrogen

Ammonia, derived largely from the deamination of amino acids, is toxic to all mammalian cells. The ammonia formed as a result of the deamination of amino acids is detoxified by one of two routes.⁸ The most important pathway involves the conversion of ammonia to urea by enzymes of the Krebs-Henseleit, or urea, cycle, which happens only in the liver (Fig. 2.10). A second route of ammonia metabolism involves synthesis of L-glutamine from ammonia and glutamate by renal glutamine synthetase.

THE CITRIC ACID CYCLE AND INTEGRATION OF METABOLIC PATHWAYS

The major function of the citric acid cycle is to act as a common pathway for the oxidation of carbohydrate, lipid, and protein. Conversely, the citric acid cycle also plays important roles in gluconeogenesis, lipogenesis, and amino acid metabolism. In the fed state, a large proportion of ingested energy from foodstuffs is converted to glycogen or fat. The metabolism of sugars, fats, and proteins, then, allows adequate fuels for all tissue types under conditions from fed to fasting to starvation. The body accomplishes production of fuel substrates for organs and regulates intestinally absorbed nutrients for tissue consumption or storage by integrating three key metabolites: glucose-6-phosphate, pyruvate, and acetyl CoA (Fig. 2.11). Each of these three simple chemical mole-

cules can be extensively modified to allow a large number of metabolites.

5 The citric acid cycle is composed of a series of mitochondrial enzyme reactions. The substrate that drives the citric acid cycle is acetyl CoA.⁹ In the mitochondria, acetyl CoA

FIGURE 2.10. The urea cycle. Ammonia entering the urea cycle is derived from protein and amino acid degradation in tissues (endogenous) and the colonic lumen (exogenous).

FIGURE 2.11. Summation of the key regulatory molecules used by the liver during diverse metabolic functions. Essentially, any compound found in the body can be synthesized in the liver from glucose-6-phosphate, acetyl coenzyme A, or pyruvate. As a consequence of the inability of mammalian liver to convert acetyl coenzyme A to pyruvate, fats cannot be converted to carbohydrates.

combines with oxaloacetate to form citrate. Through a series of enzymatic reactions involving both dehydrogenases and decarboxylases, citrate is catabolized to result in the generation of hydrogen-reducing equivalents and carbon dioxide (Fig. 2.12). Each molecule of acetyl CoA catab-

olized through the citric acid cycle yields three molecules of $\text{NADH} + \text{H}^+$ and one molecule of flavine adenine dinucleotide (FADH_2). These reducing equivalents are transported to the inner mitochondrial membrane and the electron transport chain to generate more ATP. Each molecule of $\text{NADH} + \text{H}^+$ is oxidized to yield three molecules of ATP, and each molecule of FADH_2 is oxidized to yield two molecules of ATP. One molecule of ATP is generated at the substrate level in the conversion of succinyl CoA to succinate; thus, the total molecules of ATP generated per molecule of acetyl CoA is 12.

G6P can be stored as glycogen or converted into glucose, pyruvate, or ribose-5-phosphate (a nucleotide precursor). Pyruvate can be converted into lactate, alanine (and other amino acids), and acetyl CoA, or it can enter the tricarboxylic acid cycle by conversion to oxaloacetate. Acetyl CoA is converted to HMG-CoA (a cholesterol and ketone body precursor) or citrate (for fatty acid and triglyceride synthesis), or it is degraded to carbon dioxide and water for energy. In humans, acetyl CoA cannot be converted into pyruvate due to the irreversible reaction of pyruvate dehydrogenase. Thus, lipids cannot be converted into either carbohydrates or glucogenic amino acids.

Regardless of the fed state of the human body, there is a requirement for glucose utilization. The nervous system and erythrocytes have an absolute requirement for glucose. Glucose is a source of glycerol-3-phosphate for adipose tissue, and most other tissues for integrity of the citric acid cycle. To maintain adequate glucose for survival, other fuels can be used depending on environmental conditions. Under conditions of carbohydrate shortage, ketone bodies and free fatty acids are utilized to spare oxidation of glucose in muscle. These alternate fuels increase intracellular citrate, which inhibits both phosphofructokinase and pyruvate dehydrogenase. In starvation, fatty acid oxidation results in the production of glycerol, which, along with gluconeogenesis from amino acids, is the only source of the required glucose. Ultimately, even the brain can substitute ketone bodies for about half of its energy requirements. The preferred energy substrates for liver are ketoacids derived from amino acid degradation even in well-fed states. This is designed to allow the consumption of glucose by obligate tissues. Glucose produced by the dephosphorylation of G6P rapidly diffuses out of the cell and is taken up by the brain, muscles, and other organs. Hepatic glycolysis is used primarily for the production of intermediates of metabolism and not for energy. Hepatic fatty acid degradation for energy is also inhibited under most circumstances and occurs only during adipocyte lipolysis.

FIGURE 2.12. The citric acid cycle. Reduced nicotinamide adenine dinucleotide and reduced flavin adenine dinucleotide, formed in the citric acid cycle, are subsequently oxidized in mitochondria by means of the electron transport chain to generate adenosine triphosphate. Acetyl coenzyme A plays a key role.

BIOTRANSFORMATION

Biotransformation is defined as the intracellular metabolism of endogenous organic compounds (e.g., heme proteins and

steroid hormones) and exogenous compounds (e.g., drugs and environmental compounds). Most biotransformation occurs chiefly in the liver, which contains enzyme systems that can expose functional groups, such as hydroxyl ions (phase I reactions), or alter the size and solubility of a wide variety of organic and inorganic compounds by conjugation with small polar molecules (phase II reactions). A general strategy is to convert hydrophobic, potentially toxic compounds into hydrophilic conjugates that can then be excreted into bile or urine.

- 6 The four general enzyme families responsible for hepatic biotransformation are the cytochromes P-450, the uridine diphosphate-glucuronyl (UDP-glucuronyl) transferases, the glutathione (GSH) S-transferases, and the sulfotransferases. Biotransforming enzymes are not distributed uniformly within the cells of the hepatic lobule. This heterogeneity may account for the ability of some drugs to cause damage preferentially in zone 3 hepatocytes (those nearest the central venule).

Cytochromes P-450

The cytochromes P-450 are named for their ability to absorb light maximally at 450 nm in the presence of carbon monoxide. These enzymes are bound to the ER and collectively catalyze reactions by using NADPH and oxygen. The P-450 isozymes present in mammalian liver catalyze reactions such as oxidation, hydroxylation, sulfoxide formation, oxidative deamination, dealkylation, and dehalogenation. Such reactions allow further phase II conjugation with polar groups such as glucuronate, GSH, and sulfate. The cytochromes P-450 can also create potentially toxic metabolites. Drugs such as acetaminophen, isoniazid, halothane, and the phenothiazines can be converted into reactive forms that cause cellular injury and death. The cytochromes also are responsible for the formation of organic free radicals, reactive metabolites that can directly attack and injure cellular components or act as haptens in the generation of an autoimmune response. Several of the most potent known carcinogens are aromatic hydrocarbons, which are modified by cytochromes P-450.

Uridine Diphosphate-glucuronyl Transferases

Glucuronidation is the conjugation of UDP-glucuronic acid to a wide variety of xenobiotics by either ester (acyl) or ether linkages. The transferases catalyzing these reactions reside in the ER. Many common compounds are metabolized in this way, including bilirubin, testosterone, aspirin, indomethacin, acetaminophen, chloramphenicol, and oxazepam. Clinically significant loss of activity can occur with acute ethanol exposure or acetaminophen overdose, when formation of UDP-glucuronic acid from UDP-glucose is outstripped by use. Some acyl linkages lead to the generation of electrophilic centers that can react with other proteins. The covalent linkage of conjugated bilirubin to albumin is believed to occur by this mechanism.

Glutathione S-transferases

The GSH transferases are more selective in the biotransformations they perform. GSH conjugation occurs only with compounds that have electrophilic and potentially reactive centers. The role of GSH conjugation catalyzed by the GSH S-transferases is demonstrated by acetaminophen. In metabolism of this drug, cytochromes P-450 create an electrophilic center that reacts with protein thiol groups or GSH.¹⁰ The presence of GSH S-transferase allows the preferential detoxifi-

cation of acetaminophen rather than its potentially injurious binding to thiol groups. A class of GSH S-transferases, known as *ligandins*, appears to facilitate the uptake and intracellular transport of bilirubin, heme, and bile acids from plasma to liver. In addition to the detoxification of potential toxins, GSH is a substrate for GSH peroxidase, an enzyme important in the metabolism of hydrogen peroxide.

Sulfotransferases

The sulfotransferases catalyze the transfer of sulfate groups from 3'-phosphoadenosine-5'-phosphosulfate (PAPS) to compounds such as thyroxine, bile acids, isoproterenol, α -methyldopa, and acetaminophen. They are located primarily in the cytosol. Although many P-450 derivatives can be further conjugated by either the sulfotransferases or the glucuronyl transferases, a limited ability of the liver to synthesize PAPS makes glucuronidation the predominant mechanism.

HEME AND PORPHYRIN METABOLISM

Heme is formed from glycine and succinate and is the functional iron-containing center of hemoglobin, myoglobin, cytochromes, catalases, and peroxidases. From glycine and succinate precursors, δ -aminolevulinic acid (δ -ALA) is synthesized by the rate-limiting enzyme ALA synthase. The porphyrinogens are intermediates in the pathway from δ -ALA to heme, and porphyrins are oxidized forms of porphyrinogen (Fig. 2.13). Inherited enzyme defects in the heme synthetic pathway cause the overproduction of various porphyrinogens, which can in turn cause clinical manifestations known as the *porphyrias*.¹¹ Acquired porphyria can be caused by heavy metal intoxication, estrogens, alcohol, or environmental exposure to chlorinated hydrocarbons.

Bilirubin IXa is the predominant heme degradation product in humans and is derived mostly from hemoglobin. The enzyme heme oxygenase, located in cells of the reticuloendothelial system, is primarily responsible for this conversion. Heme oxygenase resides in the ER and requires NADPH as a cofactor. Hepatic processing of bilirubin is further detailed in the section on bile formation.

METAL METABOLISM

Iron uptake appears to occur by two distinct processes: (a) receptor-mediated endocytosis of iron-transferrin complexes and (b) facilitated diffusion across the plasma membrane. More iron is taken up and stored by the liver than by any other organ, with the exception of the bone marrow. Transferrin is synthesized in the liver and has specific plasma membrane receptors on a number of different tissues. After endocytosis, the transferrin and iron dissociate and the transferrin and transferrin receptor return to the cell surface for recycling. A pathway appears to involve the dissociation of iron and transferrin at the plasma membrane and subsequent internalization by carrier-mediated diffusion. Once internalized, iron is stored and forms a complex with apoferritin. Each apoferritin molecule is capable of storing several thousand iron molecules. The iron-apoferritin complex, called *ferritin*, is responsible for iron storage under physiologic conditions. Iron storage in a protein-bound form is essential because free iron can catalyze free radical formation, leading to cell injury.¹²

Copper is transported to the liver bound to albumin or histidine and enters the hepatocytes by a process of facilitated

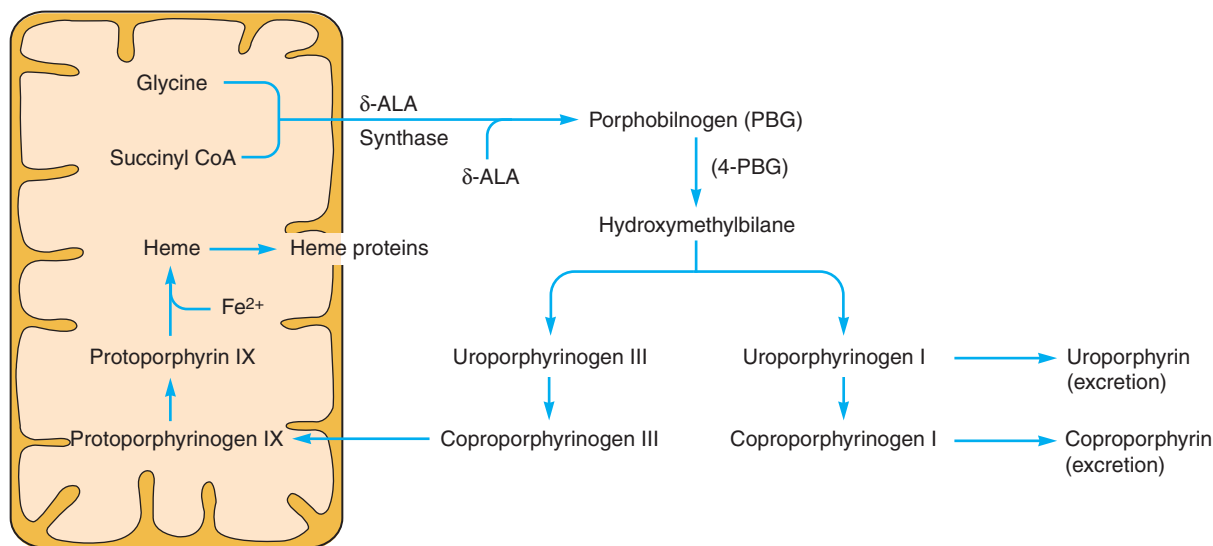

FIGURE 2.13. The heme biosynthetic pathway. Inherited defects of each of the heme biosynthetic enzymes except δ -aminolevulinic acid synthase have been described and lead to the clinical disorders known as the porphyrias.

diffusion. Once inside the cell, copper can bind to several intracellular proteins for storage or as a necessary enzyme cofactor. Copper-binding proteins include metallothionein, monoamine oxidase, cytochrome *c* oxidase, and superoxide dismutase. *Ceruloplasmin* is a liver-derived protein that binds hepatic copper for transport to other tissues. The low levels of ceruloplasmin seen in patients with Wilson disease suggest a pathogenetic defect.

Zinc is taken up by and competes for the same binding sites as copper. In hepatocytes, zinc binds predominantly to metallothionein and is excreted into bile, in which it enters the enterohepatic circulation. Other metals, usually found in trace amounts, are lead, cadmium, selenium, mercury, and nickel. These metals are usually bound to metallothionein or GSH, and intoxication is associated with free radical formation and liver injury.

INTERMEDIARY METABOLISM AND SPECIALIZED CELL FUNCTION

Once understood, the general principles of intermediary metabolism can be used to understand cell biology in specialized cell types. Several examples, not intended to be all-inclusive, are discussed to demonstrate how biochemical pathways influence cellular function.

Hepatocyte-specific Measures of Liver Reserve

To refine traditional estimates of liver reserve, such as the clinically based Childs-Pugh classification and cross-sectional imaging to quantitate liver volume, functional tests have been developed that measure the ability of an individual liver to carry out specific biochemical tasks and correlate this “functional capacity” with perioperative morbidity and mortality.¹³ Although myriad functional studies have been described, sev-

eral are known to be more predictive of liver function. None are widely used due to the lack of availability in clinical laboratories and the relatively small population of relevant patients.

Indocyanine green (ICG) is taken up by specific, ATP-independent carriers on the basolateral surface of the hepatocyte and excreted unmetabolized into bile through a mechanism that is dependent on hepatic ATP. ICG does not undergo enterohepatic recirculation. In the absence of adequate hepatocyte ATP stores, ICG builds up in and saturates hepatocytes, preventing otherwise available carriers from taking up more ICG. As a result, there is decreased clearance of ICG from serum, and clearance rates correlate with improved survival in major liver resections.¹⁴ A limitation is the dependence of ICG clearance on hepatic blood flow, which can be significantly altered in cirrhosis.

Lidocaine is converted, by hepatocytes, into monoethylglycinexylidide (MEGX). The pathway includes oxidative N-dealkylation by the cytochromes P-450, and 97% of the conversion is done in the liver. There are data that show decreased complication rates when the MEGX test is used to predict the outcome of liver resection in cirrhotics.¹⁵ The hippurate ratio is a measure of glycine conjugation of para-aminobenzoic acid to para-aminohippuric acid. These conjugations occur by non-P-450 phase II conjugation mechanisms.¹⁶ The arterial ketone body ratio (AKBR) is also used to predict outcome. The AKBR is the fasting ratio of acetoacetic acid to β -hydroxybutyric acid and reflects mitochondrial oxidized nicotinamide adenine dinucleotide to reduced nicotinamide adenine dinucleotide.¹³

Cardiac Myocyte Substrate Utilization

Under normal conditions, the heart generates 70% of its ATP from fatty acid oxidation, 30% from glucose, and the rest from oxidation of lactate, amino acids, and ketone bodies.¹⁷ In heart failure, the myocardium shifts away from fatty acid oxidation and toward glucose oxidation. This shift improves contractile function and slows the progression of pump failure.¹⁸ In cardiac surgery, during reperfusion, oxygen levels are

restored, as is function of the citric acid cycle. However, there is a shift toward greater fatty acid oxidation due to elevated levels of circulating fatty acids, release of lipoprotein lipase by heparin, and decreases in malonyl CoA.¹⁹ The substrate switch to higher fatty acid oxidation decreases glucose oxidation, worsens intracellular acidosis, and diverts use of ATP from contractility to restoring cellular homeostasis.^{17,20} Switching energy substrate metabolism from fatty acids to glucose improves myocardial efficiency. As an example, during cardiac surgery, the infusion of glucose, insulin, and potassium may stimulate the citric acid cycle; directly enhance myocardial function (through enhanced calcium sensitivity); restore myocardial glycogen stores; and cause a lowering of free fatty acids in the plasma.²¹

Metabolic Regulation of Insulin Secretion in the Beta Cell

Mammalian beta cells of the islets of Langerhans are the sole source of insulin. Insulin is secreted by a process known as stimulus-secretion coupling, which begins with glucose entering the beta cell via a specific glucose transporter known as GLUT-2. Intracellular glucose is metabolized beginning with phosphorylation by an equally unique hexokinase (glucokinase). The resulting glucose-6-phosphate is then metabolized by both glycolysis and the tricarboxylic acid cycle. The resulting ATP closes ATP-sensitive potassium channels, leading to cell membrane depolarization and opening of calcium channels. Free intracellular calcium then leads to insulin secretion.²²

A distinguishing feature of beta cells compared to hepatocytes is that beta cells contain neither lactate transporters nor lactate dehydrogenase. As a result, neither lactate metabolism nor gluconeogenesis occurs in the beta cell.²³ Essentially, all glucose-derived carbon is funneled into the citric acid cycle, where 75% of the catabolic product is ATP, and the rest is used for protein synthesis. Pyruvate is forced into the citric acid cycle by a process called *anapleurosis*, or filling up. To overcome the unfavorable kinetics of driving pyruvate through the cycle, the beta cell contains seven times the usual level of pyruvate carboxylase.²⁴

SUMMARY

The basics of intermediary metabolism have changed little over the past decade. Knowledge of the fundamental biochemical reactions by which substrates are metabolized, however, is being exploited at an ever-accelerating rate to support and perhaps enhance specialized cellular function. Variations on basic metabolic themes in individual cell types allow the development of

rational strategies to assess and improve cellular function, from the hepatocyte to the cardiac myocyte to the beta cell.

CHAPTER 3 ■ NUTRITION AND METABOLISM

J. STANLEY SMITH, Jr. AND DAVID C. FRANKENFIELD

KEY POINTS

- 1 Recognize that the goal of perioperative or post-traumatic nutritional support is repletion or maintenance of protein and energy stores as a part of lean body mass to allow recovery from illness.
- 2 Starvation and systemic inflammatory response result in erosion of the fat-free mass and body weight (malnutrition) and are indicators for nutrition support if present.
- 3 Assess the patient's nutritional status by the subjective global assessment.
- 4 Identify nutritional requirements by estimating basal metabolic rate for age, gender, and body surface area and increase by 25% to 100% based on severity of stress.
- 5 Use enteral feedings whenever possible.
- 6 Remember the inflammatory response in metabolism is found in more disease states than trauma and sepsis.
- 7 Realize that inflammation increases energy utilization and alters the metabolism of glucose, protein, fat, and trace minerals.
- 8 Supply calories as glucose and fat with a calorie to nitrogen ratio of 150:1.
- 9 A strong relation between protein depletion and postoperative complications has been demonstrated in nonseptic, nonimmunocompromised patients undergoing elective major gastrointestinal surgery.
- 10 The maintenance of an intact brush border and intercellular tight junctions prevents the movement of toxic substances into the intestinal lymphatics and circulation; these functions may become altered in critically ill patients.
- 11 Re-assess the adequacy of nutritional support to determine further needs.
- 12 Cancer or AIDS cachexia cannot be cured, only managed, and so removing the stimulus for inflammation is not possible.
- 13 Excess glucose calories are converted to fat, are deposited in the liver, and result in hyperglycemia and glycosuria.

Nutrition support is indicated in surgical patients if they are significantly malnourished prior to surgery, if they are expected to remain NPO (non per os, “nothing by mouth”) for more than 5 days postoperatively, or if they are critically ill.¹⁻⁴ The main feature of metabolism in the surgical patient is the presence of the inflammatory response. The inflammatory response is critical to survival from surgical or traumatic injury, yet it poses challenges in the nourishment of these patients. If the surgical injury is not sufficient to produce an inflammatory response, nutrition support in surgery is similar to that in simple starvation. Well-nourished patients with short-term undernutrition or mild inflammatory stress and limited weight loss do not have increased risk of complications during their surgical convalescence related to their nutritional status.¹⁻⁴ However, as America becomes more obese, good nutrition does not equate to a body weight above the ideal. In an Italian study, body mass index (BMI) and waist circumference were directly associated with systolic and diastolic blood pressure values. Processed meat, potatoes, and wine, typically consumed in the unhealthy American diet, were directly associated with increased blood pressure.⁵

- 1 The goal of nutrition support is to minimize protein loss and to provide key nutrients to maintain immune and other critical functions during and after surgical or traumatic injury. This chapter addresses the areas of nutritional assessment, metabolism, and therapy including the nutritional response to inflammation.

BASIC NUTRITIONAL METABOLIC PRINCIPLES

Body Composition

Total body mass is composed of aqueous and nonaqueous components. The nonaqueous portion is made up of bone

mineral and the lipid portion of adipose tissue. The aqueous portion is divided between the body cell mass, which is made up of cellular components of skeletal muscle, organs, skin, blood, and adipose tissue, and the extracellular fluids and proteins, such as interstitial and intravascular volume, serum proteins, tendons, ligaments, and cartilage. The body cell mass is the metabolic engine of the body, while the extracellular contents form the supporting structure for the body cell mass. Total body water makes up about 55% to 60% of total body mass. In the prototypical 70-kg male, this is 40 liters, with about 22 liters intracellular, 14 liters interstitial, and 3.0 to 3.5 liters plasma. In obesity, there is generally expansion of both the body fat mass and the fat-free mass. Body composition also varies as a function of age and gender (Fig. 3.1)⁶ and becomes further altered following injury or surgery.⁷ In clinical practice, body composition is not measured but rather inferred by using the Quetelet index, more commonly known as body mass index (kg/m^2), which is most directly a measure of the total mass as a function of weight but which generally correlates with body fatness. A body mass index of $30 \text{ kg}/\text{m}^2$ or higher is indicative of obesity. However, there are people who are obese at lower levels of body mass index and others who are not obese despite a body mass index in excess of $30 \text{ kg}/\text{m}^2$.⁸

Body composition is altered following injury or surgery. The injury-induced changes are characterized by a rapid loss of lean body mass, a slower loss of body fat, and expansion of the extracellular fluid compartment, leading to a diminution of the metabolically active tissue even as total body weight increases.⁹ The expansion of the extracellular water compartment is recognizable as edema, but the underlying changes in body cell mass and fat mass are difficult to recognize until late in the process, when they manifest as temporal or extremity wasting. Nonvisual assessment tools are limited. There is one report that midarm circumference correlates with outcomes in critically ill patients.¹⁰ Bioelectrical impedance is another way

FIGURE 3.1. Body composition as a function of gender and age. (Data from Cohn SH, Vaartsky D, Yasumura S, et al. Compartmental body composition based on total-body nitrogen, potassium, and calcium. *Am J Physiol* 1980; 239:E524–E530.)

to measure the change in lean body mass, though its utility is still under investigation.

Bioelectrical impedance operates on the principle that electrical resistance is proportional to the fluid and electrolyte content of tissue. Since the lean body mass or body cell mass contains all of the fluid and electrolyte content, passage of an electrical current is a measure of the lean body or “fat-free” mass. This appears to work well in both healthy and critically ill patients and can give the practitioner a guide to accurately gauge nutritional and fluid support, especially in those patients with expanded extracellular water and increased body weight.⁹

Obese patients have an excess store of calories, but the body protein compartment is independent of the fat store. Obese people can be just as protein depleted as underweight people (i.e., it is possible to be overnourished and undernourished at the same time).

Energy and Substrate Metabolism

Conversion of Fuel to Work. From a simplistic mechanical standpoint, the human body is much like an engine. It uses oxygen to burn fuel (carbohydrate, fat, protein, ethanol) to generate energy used to perform work, and it exhausts or excretes the byproducts of this combustion (water, carbon dioxide, and heat) to the environment (Fig. 3.2). The human body does several kinds of work essential for life including mechanical work (e.g., locomotion, breathing), transport work (e.g., carrier-mediated uptake of nutrients into cells), and synthetic work (biosynthesis of proteins and other complex

molecules). The energy used to do this work comes from the energy present in the chemical bonds of the nutrients we consume. Thus, the human body converts energy stored in the chemical bonds of nutrients into internal and external work. During starvation or following operative procedures when no nutrition is provided, the body oxidizes stored energy sources (i.e., body tissue) to generate this work. In humans, this process is relatively inefficient, since about half of this potential energy is lost as heat. Some of the heat generated during this process is used to help maintain body temperature via carefully controlled regulatory mechanisms in the hypothalamus. Excess heat is released primarily through the skin via evaporation, radiation, convection, and conduction. In surgical patients, these central regulatory mechanisms often become “reset,” leading to the development of fever that under most circumstances is an appropriate response to injury and infection. An increase in body temperature, for example, results in an increase in enzymatic reactions that are necessary to support the inflammatory process.

The Calorie. Energy (heat) is measured in joules or calories. The joule is the SI unit of energy and is defined as the energy required to exert a force of 1 Newton for a distance of 1 meter. Unit of measure is $\text{kg/m}^2/\text{s}^2$. The joule is intended to replace the calorie (technically referred to as the g-calorie) as the standard unit of energy on the basis that it is measured in metric terms. In the United States, the g-calorie or kg-calorie (kilocalorie) remains the most common way to express energy. A g-calorie is the amount of heat required to raise the temperature of 1 gram of water from 14.5°C to 15.5°C at a pressure of one standard atmosphere (and hence it can be argued that the calorie, like the joule, is a metric measurement). The kg-calorie is the amount of heat necessary to increase the temperature of 1 kg of water under the same circumstances. Joules and g-calories are small units of energy (1 joule is expended by a resting person every hundredth of a second) and so megajoules (MJ) and kilocalories are most often used in discussions of human nutrition. A megajoule is equivalent to 1,000,000 joules, while a kilocalorie is equivalent to 1,000 calories. The conversion of megajoules to kilocalories is $1 \text{ MJ} = 239 \text{ kcal}$.

Respiration and Combustion. All work performed by the body is accompanied by oxidation of fuel via a series of decarboxylation/dehydrogenation reactions (glycolysis, tricarboxylic acid cycle). The fuel is derived from food or from body tissue. The energy released by these reactions is captured in adenosine triphosphate (ATP) via a series of redox reactions (electron transport system). In the final reduction reaction hydrogen is combined with oxygen to form water. The oxygen

FIGURE 3.2. Fuel utilization in human metabolism.

TABLE 3.1 CLASSIFICATION**FUEL RESERVES OF A HEALTHY (70-kg) ADULT MALE**

ENERGY SOURCE	kg	kcal VALUE
Fat	14	125,000
Protein		
Skeletal muscle	6	24,000
Other	6	24,000
Glycogen		
Muscle	0.15	600
Liver	0.075	300
Free glucose	0.02	80

present for that reduction and the carbon dioxide produced by decarboxylation are transported by the circulatory system and exchanged with the atmosphere by the lungs. Protein oxidation is a special case in which nitrogen is a byproduct besides carbon dioxide and water. The nitrogen is removed by the kidney after conversion to urea by the liver.

Body Fuels. Human metabolism is arranged such that the fuels consumed in the diet are preferentially utilized when they are present, with excess stored for the postprandial period. In the postprandial state, the body contains fuel reserves that it can mobilize in an orderly fashion as the time of fasting increases. These same fuel reserves are tapped during stress metabolism, though in a less orderly fashion (Table 3.1). By far the greatest energy component is calorically dense fat, providing 9 kcal/g. The body can store almost limitless amounts of fat. Body protein comprises the next largest source of potential energy, but amino acids yield only about 4 kcal/g, and the total reserve is smaller. Unlike fat reserves, body protein is a structural and functional component of the body. There is no storage form. Loss of body protein, if severe, has functional consequences. In undernourished and underfed states, proteolysis is mildly accelerated to generate amino acids to support gluconeogenesis and other key synthetic processes. In the long run, a chronic catabolic state can lead to erosion of body protein stores such that susceptibility to infection is increased, wound healing is impaired, and outcome is unfavorably impacted. Carbohydrate stores are minimal and exist as glucose or liver glycogen and can be depleted quickly unless replenished from exogenous sources. Though limited in stores, there is constant demand for carbohydrate in stress metabolism. Thus, carbohydrate and protein metabolism are linked because the body draws on endogenous protein to produce new glucose to meet the demand unmet by diet.

Carbohydrate

The basic unit of carbohydrate metabolism in humans is glucose. Nearly all dietary carbohydrate is converted to glucose, and glucose is the form of carbohydrate for oxidation. The human body has a constant need for glucose oxidation in the central nervous system and blood cells. A glucose supply of approximately 12 hours is available as liver glycogen, which is sufficient to cover glucose needs between meals. In periods of fasting extending beyond the glycogen supply, the body converts amino acids to glucose, recycles the available glucose, and eventually induces ketone production from fat, which can substitute for some but not all of the body's glucose need. Resumption of glucose intake completely reverses these metabolic adaptations. In surgical nutrition, the inflammatory

response accelerates the rate of glucose production from amino acids, minimizes glucose recycling, and limits ketone production, leading to pronounced gluconeogenesis from amino acids. These metabolic adaptations are much less responsive to dextrose infusion after surgery or injury than in simple starvation.

Lipid

Lipids consist of a wide variety of hydrocarbon chains that can be classified several ways, including by chain length, degree of saturation, and location of the first double bond. Perhaps the most useful way to classify lipids for surgical nutrition is by chain length.

Short-chain fatty acids (two- to five-carbon chain length) are derived from the fermentation of dietary fiber in the colon. Much of this short-chain fatty acid is used by the commensal bacteria and is important in maintaining a healthy environment in the colon (i.e., optimal pH and bacterial populations). Some of the short-chain fatty acids are absorbed and are preferred fuels for the colonocytes. Short-chain fatty acid absorption is attended by absorption of water and sodium.

Medium-chain fatty acids (six- to nine-carbon chain length) are not typically found in the human diet but are used widely in enteral nutrition products (they are manufactured by fractionating the fatty acids of coconut oil). They are used because they are easier to digest and absorb than long-chain triglycerides. Being water soluble, medium-chain triglycerides do not require emulsification or micelle formation. Lipase is not required. The medium-chain triglycerides are absorbed directly into the portal circulation rather than via the lacteals into the lymphatic system. They yield 8.0 kcal/g on oxidation.

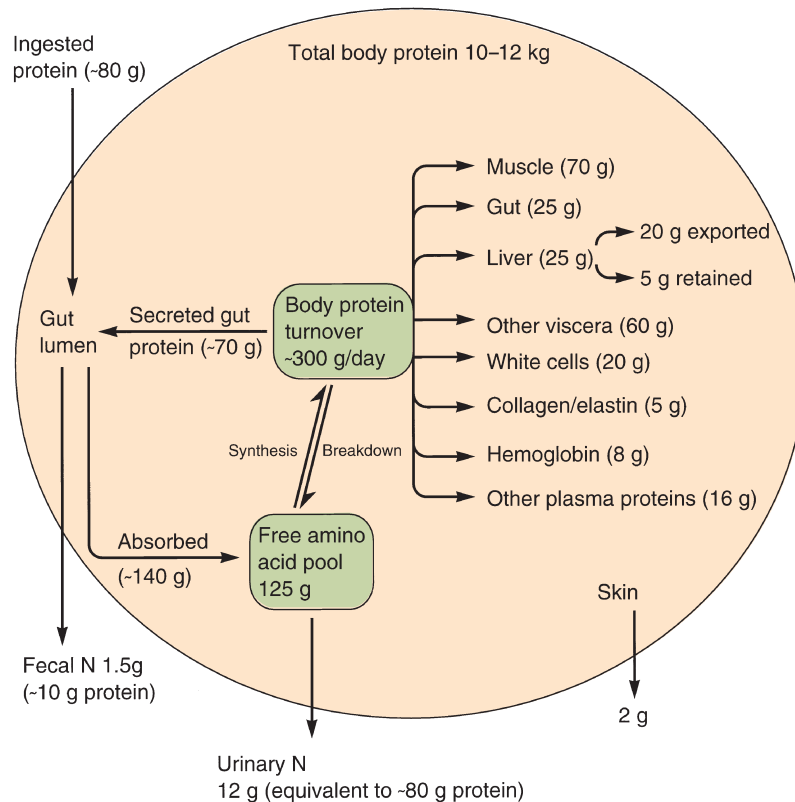

Long-chain fatty acids (greater than nine-carbon chain length) include the two fatty acids that are dietarily essential (linoleic and linolenic acid); are water insoluble; require bile salts for emulsification, lipase for digestion, and micelle and chylomicron formation for transport; and gain access to the bloodstream via the thoracic duct. In the cell, lipoprotein lipase is necessary for uptake, and carnitine is required to move the fatty acid from the cytosol into the mitochondria for oxidation. Long-chain triglycerides are the body's main form of energy storage. Some of the long-chain fatty acids are precursors for important inflammatory mediators (prostaglandins, leukotrienes, thromboxanes). The type of eicosanoid produced is partly influenced by the type of fatty acid available, and the type of fatty acid available is influenced by dietary fat intake.

Protein

Protein is a key nutrient in surgical nutrition and differs from carbohydrate and fat because it contains nitrogen. Twenty different amino acids are dietarily essential, and the quality of a food protein is determined by its content of these 20 amino acids. Proteins can be categorized structurally as amino acids, peptides, and proteins. The human gastrointestinal (GI) tract can absorb amino acids and small peptides, and must digest intact proteins into these smaller sizes for absorption. Protein is not stored by the body. All protein is functional.

Absorbed amino acids pass first through the liver, where portions are extracted for synthesis of circulating proteins. The branched-chain amino acids (leucine, isoleucine, and valine) are untouched by the liver and so are transported to and extracted by muscle. Dietary and endogenous amino acids eventually mix and distribute into intracellular and extracellular amino acid pools, where they are available upon demand for further metabolism. Excess amino acids are degraded and their carbon skeletons are oxidized to produce energy or are incorporated into glycogen or free fatty acids. In addition to

FIGURE 3.3. Whole body protein metabolism in a normal 70-kg man.

the metabolism of dietary amino acids, the existing proteins in the cell are continuously recycled, such that total protein turnover in the body is about 300 g/day (Fig. 3.3). Vertebrates cannot reutilize nitrogen with 100% efficiency; therefore, obligatory nitrogen losses occur, mainly in the urine. Most of the nitrogen lost in the urine is in the form of urea (85%), with

lesser amounts excreted as creatinine and ammonia. Urinary nitrogen losses diminish in individuals fed a protein-free diet but never reach zero because of the body's inability to completely reutilize nitrogen. In stressed patients, this ability to adapt to starvation is compromised such that proteolysis of body proteins continues at a substantial rate (Fig. 3.4).

FIGURE 3.4. The response to starvation in normal, postoperative, and septic individuals. The normal person adapts to starvation by conserving body protein, which is manifested by a decrease in nitrogen excretion in the urine. Septic patients do not adapt to starvation by using ketones for energy and therefore urinary nitrogen losses are much greater.

Although it is often assumed that skeletal muscle bears the brunt of this protein wasting, it is now apparent that net proteolysis also occurs in organs such as the gut and liver. If the ability to synthesize proteins is compromised by malnutrition or disease, function is generally correspondingly impacted. This may show clinically in patients as impaired wound healing, immunoincompetence, or breakdown of the gut mucosal barrier.

Metabolism of amino acids (from enteral or parenteral feedings) generates ammonia, which is one of the most toxic and reactive compounds in physiologic fluids. Yet, ammonia levels in blood are generally kept at nontoxic concentrations (20 to 40 μM); this is done primarily in the liver by converting ammonia to urea, a nontoxic soluble compound. A large portion of the ammonia used for urea synthesis arises from nitrogen catabolism in extrahepatic tissues. Excretory or transport amino acids, primarily glutamine and alanine, serve as vehicles for transporting ammonia in a nontoxic form from peripheral tissues to the visceral organs. In these organs, ammonia is reformed and then either excreted (via kidneys, where it acts as an important buffering system) or detoxified to urea (liver). From the intestinal tract, the large ammonia load delivered to the liver escapes the systemic circulation because of the biochemical pathways in the liver that detoxify it. Only the liver has all the enzymes of urea synthesis, and these enzymes are located only in periportal hepatocytes. Thus, diseases affecting the periportal areas lead to an increased ammonia load into the systemic circulation.

Nutrition Assessment

Metabolism is altered to varying degrees by surgical injury. In many cases, these alterations are adaptive, short-lived, and sustainable by a previously well-nourished person, even if they are denied food for a few days after surgery. However, in patients with preexisting malnutrition or with sufficiently severe metabolic insult in response to surgical injury or infection, early resumption of a nutrient supply is important in maximizing their recovery and minimizing their complication risk.¹⁻⁴ The aim of nutrition assessment is to identify the patient in need of early resumption of metabolic support and to determine the nutrient requirements to be fed to the patient.

- 2 Starvation versus Inflammation as the Cause of Malnutrition.** Starvation and systemic inflammatory response result in erosion of the fat-free mass and body weight (malnutrition) and are indicators for nutrition support if present.¹⁻⁴ In starvation, the main features are reduced or absent nutrient intake with gradual loss of lean mass and body fat, preservation of serum protein levels, and reversal of the metabolic response upon feeding. The usual causes of starvation are functional (dysphagia, nausea, emesis, malabsorption) and psychosocial (food insecurity, social isolation, depression).

The main metabolic features of inflammatory response are elevated metabolic rate (hypermetabolism and hypercatabolism), an acute-phase protein response, and reduced sensitivity of the metabolic state to reversal by feeding. Impaired intake might also be present with an inflammatory response (i.e., the anorexia of illness). Inflammatory response is often the cause of malnutrition in patients with recent acute illness or chronic illness (e.g., cardiac cachexia, cancer cachexia).

- 3 Subjective Global Assessment.** Subjective global assessment is a valid way to determine whether tissue erosion has occurred and whether the etiology is starvation or inflammation.^{11,12} Subjective global assessment utilizes several types of information, including physical examination, weight history, recent nutrient intake, gastrointestinal symptoms, and history of disease. The patient is classified as class A (not malnour-

ished), class C (definitely malnourished), or class B (all other cases that are moderate or indeterminant). A typical patient with class C malnutrition has a history of unintentional weight loss and physical signs of tissue erosion (temporal and/or extremity). The etiology (starvation vs. inflammation) is important to note, but it does not have a bearing on the classification of malnutrition severity.

Serum Proteins. Although still commonly used as markers of malnutrition, serum transport proteins usually do not decrease in response to starvation, even in advanced cases. When these proteins are decreased, it is usually a sign that the patient has had or continues to have an inflammatory response.¹³ One of the features of inflammation is reprioritization of hepatic protein synthesis away from the transport proteins in favor of acute-phase reactants. C-reactive protein is an example of an acute-phase reactant that rises rapidly with inflammation and quickly falls back to normal when inflammation resolves.¹³

Nitrogen Balance. Nitrogen balance is an indicator of whether protein intake is keeping up with protein catabolism, and it may be the most important nutrition test in patients receiving nutrition support. Nitrogen balance is calculated from the amount of nitrogen consumed minus the amount excreted in a 24-hour period. Nitrogen intake is estimated from protein intake ($\text{g protein}/6.25$). The main route of nitrogen excretion is the urine (90% or more). Nitrogen is also lost through the skin and stool, but this loss is usually very small (<2 g/day), difficult to measure, and therefore usually accounted for with a constant of 2 in the balance equation. It is ideal to quantitate total urinary nitrogen (TUN), but many laboratories only measure urea nitrogen. If urea nitrogen (UUN) is measured, an additional 2 to 3 g should be added to the output side of the nitrogen balance equation to account for these unmeasured losses:

$$\text{Nitrogen balance (g/d)} = \text{Protein intake}/6.25 - (\text{TUN} + 2)$$

$$\text{Nitrogen balance (g/d)} = \text{Protein intake}/6.25 - (\text{UUN} + 2 + 3)$$

A nitrogen balance of -2 to $+2$ g/day indicates nitrogen equilibrium, and is the goal in surgical nutrition. Balances more negative than this should be managed by increasing the protein intake, and balances more positive than this are suggestive of error in the measurement (positive balance implies anabolism, but bedridden patients undergoing inflammatory response should not be anabolic). Limitations of the nitrogen balance technique include that it does not show when protein is being overfed, it takes several days for nitrogen to re-equilibrate in the body after protein intake has been changed, and renal dysfunction and GI bleeding may invalidate the study (renal dysfunction due to incomplete excretion of urea nitrogen, GI bleeding due to excess urea nitrogen production not associated with metabolism). Surgical critical care patients tend toward negative nitrogen balance unless large amounts of protein are administered,¹⁴ and achievement of positive nitrogen balance has been linked to improved outcome, at least in one narrow segment of critically ill patients.¹⁵

Indirect Calorimetry. Resting energy expenditure can be measured at the bedside with indirect calorimetry. Patients must be either intubated or able to tolerate a hood placed over their face for collection of exhaled breath. Intubated patients must have a fraction of inspired oxygen less than 60%, while spontaneously breathing patients must be breathing room air only (no nasal cannulas, face masks, continuous positive airway pressure [CPAP] machines, etc.). No air leaks can be present. Protocols have been developed to measure resting energy expenditure with just a 5-minute test period (requiring a tight 5% coefficient of variation on the minute-to-minute measures of gas exchange), which saves time yet yields a reliable figure for 24-hour resting energy expenditure. If this 5% steady-state

threshold is not met, a longer 30-minute measurement accepting a 10% coefficient of variation is accurate. These guidelines cover other aspects of measurement including environmental conditions, body posture, physical motion, feeding state, and interpretation of respiratory quotient.¹⁶

- 4 **Estimation of Metabolic Rate.** In most cases, energy expenditure is not measured, but estimated. Estimation of energy expenditure relies on the fact that all metabolic activity occurs within the fat-free mass. Fat-free mass is a function of body weight, height, age, and sex, and therefore, resting energy expenditure is likewise predictable from these variables. In obesity, these relationships are preserved, but the strength of the relationships is diminished. Several equations exist for predicting resting energy expenditure from these variables. For healthy people, the Mifflin-St. Jeor equation appears to be accurate more often than any of the other equations in existence (Table 3.2).¹⁷ In non-intensive care unit (ICU) adult surgical patients without significant inflammatory response, this equation can probably be used without modification. In the more complex situation of critical illness, equations developed for this special population, taking into account the effect of inflammation on metabolic rate, improve the accuracy of calorie prediction and thus are better guides to calorie replacement (Table 3.3).^{18,19} In general, energy needs increase with

the presence of inflammatory response (Table 3.4).²⁰ Interestingly, the expenditure of kilocalories is only minimally increased after elective surgery. The largest increase in energy expenditure occurs in patients with severe multiple trauma or major thermal injury. However, the average-sized adult who sustains even a major burn rarely increases his or her energy expenditure to more than 3,000 kcal/day.

Overfeeding

While the provision of enough calories is beneficial, giving too many calories can “overfeed” the patient. Excess calories, especially in the form of sugars, lead to lipogenesis and hepatic steatosis interfering with hepatic function. To avoid overfeeding, critically ill patients may not fit the factors used to estimate their energy requirements and require indirect calorimetry to more accurately measure energy expenditure. There are two major consequences of overfeeding, hypophosphatemia and steatosis.

Nutrition Interventions

Elective Patients. Most patients undergoing elective operations are adequately nourished. Unless the patient has suffered significant preoperative malnutrition (subjective global assessment class C) or has a major intraoperative or postoperative complication, intravenous solutions containing 5% dextrose may be administered for 5 to 7 days before the return of feeding with no detrimental effect on outcome. Therefore, the increased cost of feedings and the potential complications associated with intravenous nutrition cannot be justified. On the other hand, malnourished patients should not be left unfed for more than a day or two after surgery. Assessment of nutritional status therefore should be completed early so that this information can be integrated into decision making and nutrition care planning. Enteral feeding is preferred to parenteral nutrition in patients who cannot resume an oral diet. Standard high-protein feeding formulas are adequate. Choice of product and volume of feeding are based on the results of the nutrition assessment. Most tube feedings today are manufactured with water-soluble dietary fiber, and the use of this nutrient should be standard in the feeding of surgical patients. If fluid intake must be limited, there are standard feeding formulas with a calorie concentration of 2.0/mL.

Critical Care. Timing and feeding route are primary considerations in nutrition intervention in the critically ill surgical

TABLE 3.4

CLASSIFICATION

METABOLIC RATES OF CRITICALLY ILL PATIENTS CATEGORIZED BY REASON FOR ADMISSION VS. FEVER STATUS (MEASURE OF RESTING ENERGY EXPENDITURE/HARRIS-BENEDICT ESTIMATE OF RESTING METABOLIC RATE)

REASON FOR ADMISSION	FEVER STATUS		REASON FOR ADMISSION MEANS
	T _{max} >38°C	T _{max} <38°C	
Trauma	145 + 22	123 + 14	134 + 23
Surgery	138 + 22	125 + 14	132 + 22
Medical	139 + 20	125 + 20	132 + 20
Fever status means	141 + 24	124 + 17	

No significant difference among the reasons for admission, the difference by fever status $p < 0.0001$, and no significant fever \times reason for admission interaction.

Data from Frankenfield DC, Smith JS, Cooney RN, et al. Relative association of fever and injury with hypermetabolism in critically ill patients. *Injury* 1997;28:617.

patient. The best outcomes are achieved with enteral feeding started within 24 to 48 hours. Independent of nutritional status, any critically ill patient who is not expected to resume oral feeding within 5 days should be started on nutrition support within 48 hours.

Priorities of Care. Resuscitation, oxygenation, and arrest of hemorrhage are immediate priorities for survival. Wounds should then be repaired or stabilized as expeditiously as possible. Nutritional support is an essential part of the metabolic care of the critically ill trauma patient and should be instituted before significant weight loss occurs. Adequate nutrition supports normal responses that optimize wound healing and recovery.

- 5 At least four evidence-based guides to nutrition practice in critical care exist.¹⁻⁴ There is general agreement among the guidelines that enteral nutrition is preferable to parenteral, that feeding should be started within 24 to 48 hours and should not be supplemented with parenteral nutrition as long as some tube feeding is tolerated, that blood glucose can be controlled to less than 140 mg/dL, that blue food dye should not be used for detection of aspiration, that the head of the bed should be elevated to 45 degrees to minimize aspiration risk, and that gastric feeding routes are as good as postpyloric routes unless the stomach is proven to be dysfunctional.

There is some divergence on whether immune or inflammation-modulating feeding formulas are indicated in some critically ill patients. There is at least one quality paper that has been published since the guidelines that supports the use of such feedings in patients with sepsis and risk for acute respiratory distress syndrome (ARDS) or acute lung injury.²¹

THE BODY'S RESPONSE WHEN STRESSED BY INJURY OR SURGERY

In the 1930s, Cuthbertson²² described the time course for many of the posttraumatic responses and two distinct periods were identified. The early “ebb” or shock phase was usually brief in duration (12 to 24 hours) and occurred immediately following injury. Blood pressure, cardiac output, body temperature, and oxygen consumption were reduced. These events were often associated with hemorrhage and resulted in hypoperfusion and lactic acidosis. With restoration of blood volume, ebb phase alterations gave way to more accelerated responses. The flow phase was then characterized by hypermetabolism, increased cardiac output, increased urinary nitrogen losses, altered glucose metabolism, and accelerated tissue catabolism.

The “flow” phase responses to accidental injury are similar to those that occur following elective operation. The response to injury, however, is usually much more intensive and extends over a long period of time.

Characteristics of the Flow Phase of the Injury Response

Hypermetabolism. Hypermetabolism is defined as an increase in basal metabolic rate (BMR) above that predicted on the basis of age, sex, and body size in a healthy person. Metabolic rate is usually determined by measuring the exchange of respiratory gases and by calculating heat production from oxygen consumption and carbon dioxide production. The degree of hypermetabolism (increased oxygen consumption) is generally related to the severity of the inflammatory response to the injury, with temperature serving as a reasonable indicator of the higher metabolic rate.¹⁶

Altered Glucose Metabolism. Hyperglycemia commonly occurs following injury, and the elevation of fasting blood sugar levels generally parallels the severity of stress in the ebb phase. During the ebb phase, insulin levels are low and glucose production is only slightly elevated. Later, during the flow phase, insulin concentrations are normal or elevated; yet, hyperglycemia persists. This phenomenon suggests an alteration in the relationship between insulin sensitivity and glucose disposal, hence insulin resistance. Hepatic glucose production is increased and studies show that much of the new glucose generated by the liver arises from three-carbon precursors released from peripheral tissues.

Measurements of substrate exchange across injured and uninjured extremities of severely burned patients indicate that glucose is used in small amounts by the uninjured extremity. In contrast, the injured extremity extracts large amounts of glucose. The wound converts most of the glucose to lactate, which is recycled to the liver in the Cori cycle. Additional studies have shown that uninjured volunteers (controls) are able to dispose of an exogenous glucose load much more readily than injured patients. Moreover, the quantity of insulin elaborated by the injured was greater than in control subjects; nonetheless, these rising insulin concentrations failed to increase glucose clearance in these patients (insulin resistance). Other studies have demonstrated a failure to suppress hepatic glucose production in trauma patients during glucose loading or insulin infusion. Either of these perturbations usually inhibits hepatic glucose production in normal subjects. Thus, profound insulin resistance occurs in injured patients.

Alterations in Protein Metabolism. Extensive urinary nitrogen loss occurs following major injury. Like other responses, the loss of nitrogen following injury is related to the extent of the trauma. But it also depends on the previous nutritional status, as well as the age and gender of the patient, because these factors determine the size of the muscle mass. In unfed patients, protein breakdown rates exceed synthesis, and negative balance results. Providing exogenous calories and nitrogen increases protein synthesis, but, even with achievement of energy balance, the nitrogen loss is not attenuated.²³ Only providing enough nitrogen intake can balance the nitrogen loss.

Skeletal muscle is the major source of the nitrogen that is lost in the urine following extensive injury. Although it is now recognized that amino acids are released by muscle in increased quantities following injury, it has only recently been appreciated that the composition of amino acid efflux does not reflect the composition of muscle protein. The release is skewed toward glutamine and alanine, each of which comprise about one third of the total amino acids released by skeletal muscle, even though they make up only 5% of the protein mass of muscle. The kidney extracts glutamine, where it contributes ammonium groups for ammonia generation, a process that excretes acid loads. The gastrointestinal tract also takes up glutamine to serve as an oxidative fuel and substrate for RNA synthesis. The gut enterocytes convert glutamine primarily to ammonia and alanine, and these two substances are released into the portal venous blood. This ammonia is then removed by the liver and is converted to urea, and the alanine may be removed by the liver and serve as a gluconeogenic precursor. Following elective surgical stress, glutamine consumption by the bowel and the kidney is accelerated in a reaction that appears to be regulated by the increased elaboration of the glucocorticoids. Although skeletal muscle releases alanine at an accelerated rate, the gastrointestinal tract and kidney also release increased amounts of alanine. The alanine is then extracted by the liver to be used in the synthesis of glucose and acute-phase proteins. Hence, glutamine and alanine are important participants in the transfer of nitrogen from skeletal muscle to visceral organs; however, their metabolic pathways favor the production of urea and ammonia, both of which are terminal uses of nitrogen and must be excreted from the body.

Alterations in Fat Metabolism. To support the hypermetabolism, increased gluconeogenesis, and interorgan substrate flux, stored triglyceride is mobilized and oxidized at an accelerated rate. Glucose administration poorly attenuates this lipolysis, which may be the result of continuous stimulation of the sympathetic nervous system. Although mobilization and

use of free fatty acids are accelerated in injured subjects, ketosis during brief starvation is blunted, and the accelerated protein catabolism remains unchecked. If unfed, severely injured patients rapidly deplete their fat and protein stores. Such malnutrition increases their susceptibility to added stresses of hemorrhage, surgery, and infection and may contribute to organ system failure, sepsis, and death.

Homeostatic Responses and Adjustments to Stress

Built into the body's defense mechanism is a complex and complicated set of orchestrated responses initiated within moments of injury or insult. These responses are essential for survival and are designed to maintain body homeostasis at a time when key physiologic processes are threatened. These responses are immediately set into motion by various components of the injury response such as volume loss, tissue damage, fear, and pain. Later factors reinitiating or perpetuating these responses include invasive infection and starvation. These events are generally related to the severity of injury; that is, the greater the insult is, the more pronounced the specific response. The synthesis of key hormones and peptides allows the body to respond to such insults with remarkable resilience. From an evolutionary standpoint, these biologic responses result from a process favoring survival of the fittest in the struggle to preserve the species. From a teleologic standpoint, these responses are designed to benefit the organism, enhance recovery, and ensure a relatively speedy return to health.

Whether the body is injured accidentally or within the carefully monitored confines of an operating room, the responses to such trauma are similar. However, such settings are also different in ways that influence the extent and magnitude of the stress response (Table 3.5). Accidental injury is unplanned and uncontrolled; tissues are torn, ripped, bruised, and contaminated. The associated volume loss may be substantial, leading to tissue hypoperfusion, which, if prolonged, results in cellular deterioration and death in tissues that were not initially traumatized. Pain, excitement, and fear are generally heightened and uncontrolled. As a consequence, the magnitude of the physiologic response to major accidental injury is considerable.

In contrast, the "elective" tissue trauma that is inflicted within the confines of an operating room is calculated, planned, and monitored. Although elective surgery causes pain, often interrupts food intake, and is generally associated with the removal of an organ or tissue, the perioperative management of elective surgical patients is often designed to attenuate such

TABLE 3.5

DIFFERENCES BETWEEN ELECTIVE SURGERY AND ACCIDENTAL INJURY

■ INSULT	■ ELECTIVE OPERATION	■ ACCIDENTAL INJURY (TRAUMA)
Tissue damage	Minimal; tissues are dissected with care and reapproximated	Can be substantial; tissues usually torn or ripped; debridement often necessary
Hypotension	Uncommon: preoperative hydration employed and fluid status is carefully monitored intraoperatively	Fluid resuscitation often not immediate; blood loss can be substantial leading to shock
Pain/fear/anxiety	Generally can be alleviated with preop medication	Generally present
Infectious complications	Uncommon; prophylactic antibiotics often administered	More common due to contamination, hypotension, and tissue devitalization
Overall stress response	Controlled and of lesser magnitude; starvation better tolerated	Uncontrolled; proportional to the magnitude of the injury; malnutrition poorly tolerated

FIGURE 3.5. Relative rates of protein synthesis and breakdown in skeletal muscle in postabsorptive, postprandial, and catabolic states. After an overnight fast, muscle releases net amounts of amino acids to help maintain circulating pool. Breakdown exceeds synthesis, although this may not be measurable using standard techniques. Following a meal, muscle amino acid uptake is greater than release and protein synthesis is greater than catabolism. In the catabolic surgical patient, protein synthesis may be increased, but this rate is exceeded by the rate of breakdown. In the absence of nutritional support, profound muscle wasting can occur.

changes. Patients are assessed prior to surgery by anesthesiologists and surgeons to determine the need for preoperative nutritional support or additional medical consultation. Hydration prior to surgery is common, as is the administration of prophylactic antibiotics and drugs to relieve anxiety and fear. In the operating theater, the surgical site is “prepped” in a sterile fashion to minimize contamination, and numerous physiologic responses (i.e., blood pressure, pulse, urine output) are continually monitored. Blood and blood products are invariably available. During the operation, tissues are carefully dissected and incised to minimize tissue trauma; tissues are reapproximated with care when possible. Appropriately selected pharmacologic agents are used to block undesirable cardiovascular responses, and specific techniques such as epidural or local block anesthesia or patient-controlled analgesia are effective in minimizing postoperative pain. As a consequence, the physiologic responses to elective surgery are generally of a lesser magnitude than those following major

accidental injury (Fig. 3.5). Improvements in surgical and anesthetic care now allow us to perform major elective operations with minimal morbidity and mortality. However, in the critically ill, an inflammatory cascade is launched, reaching beyond the limits of the beneficial response.

The Inflammatory Response. The response to operative stresses (elective injury) or accidental injury (trauma) is composed of two components: a neurohormonal arm and an inflammatory arm. These pathways work together to determine the magnitude of the response. The principal counterregulatory hormones involved are the catecholamines, the corticosteroids, and glucagon. The inflammatory component of injury involves the local elaboration of cytokines and the systemic activation of humoral cascades involving complement, eicosanoids, and platelet-activating factor (Fig. 3.6). These mediators promote wound healing by stimulating angiogenesis, white cell migration, and ingrowth of fibroblasts. During

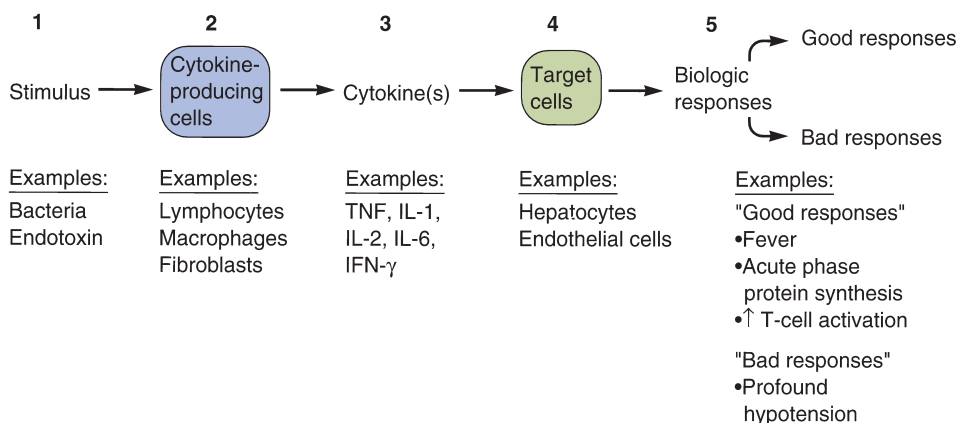

FIGURE 3.6. Cytokines can elicit both beneficial and deleterious responses.

elective surgical procedures, the local inflammatory response is confined to the wound and significant amounts of these mediators do not gain access to the systemic circulation. Following accidental injury where there is massive tissue destruction or prolonged hypotension leading to cell injury, these substances may be produced locally in the wound in excessive amounts, resulting in “spillover” into the systemic circulation. In addition, cells in other tissues (such as Kupffer cells in the liver) may become activated to produce these mediators. Such responses can lead to a systemic response in which these mediators cause detrimental effects such as hypotension and organ dysfunction.

6 The inflammatory response is the major metabolic feature of injury and infection, and is one of the main reasons why nutrition support in such patients can be a challenge. Now we are starting to appreciate the extent to which the inflammatory response underlies the nutritional issues of chronic diseases.^{24,25} An inflammatory component exists in the body composition changes of such disparate diseases as congestive heart failure, cancer, chronic obstructive pulmonary disease, human immunodeficiency virus (HIV), and rheumatologic disorders.^{26–29} Recognition that inflammation drives what has been traditionally thought of as purely nutritionally related effects of disease opens a whole new avenue for the management of the body wasting of disease (cachexia).

The inflammatory response is a primitive, complex, and indispensable part of the nonspecific immune system.³⁰ Importantly, the changes in body composition caused by inflammation are part of an orchestrated response by the body to the acute challenge to homeostasis.

Inflammation occurs at different levels. Small-scale localized inflammatory responses are occurring frequently in the body with no systemic consequences.³⁰ In fact, such responses may be an important mechanism for increasing the controlled exposure of the cellular immune system to antigen. Moderate inflammation is still localized, but its effects are more obvious. This would best be illustrated by the body’s response to a piece of foreign material (e.g., a wood splinter), in which the classic signs of inflammation might be observed: rubor, tumor, calor, dolor, and functio laesa (redness, swelling, pain, heat, and loss of function).³⁰ Multiple traumatic/surgical injury produces a more exuberant inflammation, and systemic effects are more likely to be manifest (hypermetabolism, body protein catabolism, insulin resistance, fever, acute-phase protein response). However, dysregulation of this response causes the uncontrolled inflammation of septic multiple organ failure, in which widespread endothelial damage and organ dysfunction occur, along with deranged intermediary metabolism and, sometimes, cellular immune function collapse.^{30,31} This type of inflammation-driven illness is a major cause of death in the ICU.³⁰ Severe loss of lean body mass is a feature of patients who survive this, but once convalescence is achieved, the inflammatory metabolism can normalize and the body can be replenished with proper nutrition and exercise.

7 The inflammatory response, for reasons not fully understood, can convert from an acute to a chronic condition, in which the systemic manifestations of altered acute-phase protein synthesis, impaired intermediary metabolism, and cachexia are present.³² This form of inflammation is believed to be maladaptive, and is a common feature of many preexisting chronic disease states that occur in surgical patients, such as renal failure, hepatic failure, congestive heart failure, rheumatoid diseases, and cancer. Aging and obesity also have inflammatory features that contribute to the changes in body composition, function, and health.

Teleologically, the inflammatory response seems to have evolved as a defense mechanism for short-term (5 to 7 days) challenges to homeostasis, such as trauma or infection. As people began to live healthier lives and to survive acute illness, chronic illnesses became more common. Many of these chronic conditions stimulate the inflammatory response in a chronic manner, which is probably counter to its “purpose.” Thus, while inflammation is an important component of recovery

from acute illnesses, in chronic illness it can become pathologic, leading to malnutrition.

Despite the costs to the body, the advantages of the inflammatory response are (a) rapid mobilization of fuel and substrates from muscle and adipose tissue to maximize visceral functions leading to recovery (gluconeogenesis, glutamine synthesis, acute-phase protein synthesis), (b) initiation of the process of local control and elimination of the offending agent (fever response, neutrophil and macrophage recruitment), (c) presentation of signals to the specific immune system in order to induce its participation in elimination of the offending agent, and (d) reduction of fluid loss to maintain hydration in the face of interrupted intake. In other words, the inflammatory response is a crude form of internal nutrition support, fluid resuscitation, and antibiotic therapy.

Inflammation is mediated by a host of biochemicals, including hormones, growth factors, enzymes, kinins, complement, cytokines, and eicosanoids. The initial injury stimulates local mast cells to release numerous mediators.³³ Chief among these mediators are the cytokines and eicosanoids. There are pro- and anti-inflammatory forms of each of these. The proinflammatory forms predominate early (tumor necrosis factor [TNF], interleukin [IL]-1, IL-6, prostaglandin-2 series [PGE₂], leukotriene-4 [LT₄]). TNF and the prostaglandins are expressed early and along with IL-1 elicit the acute-phase response (fever, acute-phase protein synthesis, insulin resistance). The TNF and IL-1 peak early and then disappear from plasma, but first they stimulate IL-6 release. One of the effects of IL-6 is to reduce the level of insulinlike growth factor 1 (IGF-1), which leads to proteolysis and amino acid release from muscle (Fig. 3.6).

Early in the inflammatory process, there is a marked rise in the elaboration of the counterregulatory hormones glucagon, glucocorticoids, and epinephrine. During the ebb phase of injury, the sympathoadrenal axis helps maintain the pressure-flow relationships necessary for an intact cardiovascular system to maintain blood flow in a low-volume state. With the onset of hypermetabolism, a characteristic of the flow phase, these and other hormones exert a variety of metabolic effects. Glucagon along with insulin resistance has potent glycogenolytic and gluconeogenic effects on the liver, which signal the hepatocytes to produce glucose from hepatic glycogen stores and gluconeogenic precursors. Cortisol mobilizes amino acids from skeletal muscle and increases hepatic gluconeogenesis. The catecholamines stimulate hepatic glycolysis and gluconeogenesis and increase lactate production from peripheral tissues (skeletal muscle). Catecholamines also increase metabolic rate and stimulate lipolysis. The level of growth hormone is elevated, but there is resistance to its action (possibly because of suppressed levels of IGF-1), and thyroid hormone levels are reduced to low-normal concentrations.³³ Infusion of counterregulatory hormones into normal subjects reproduces many of the metabolic alterations that are characteristic of injury.³⁴

As the inflammatory stimulus is controlled and eliminated, the anti-inflammatory cytokines (IL-4, IL-10, IL-13) and eicosanoids (PGE₃, LT₅) begin to predominate, and bring the inflammatory response to a conclusion. This is not to say that only pro- or anti-inflammatory mediators are being expressed. Rather, there is interplay between the two types of mediators, which tips in favor of the anti-inflammatory molecules as inflammation resolves.

The genes that regulate cytokine biosynthesis are highly conserved, indicating that these peptides confer a survival advantage following injury.³³ Although excess production can be dangerous to the host, cytokines exert a number of beneficial nutritional effects under the majority of circumstances, which appear to outweigh the detrimental effects that occur in extreme pathophysiologic states.

Mobilization of Amino Acids and Stimulation of Acute-phase Protein Synthesis. Cytokines act in concert with other mediators to promote mobilization of amino acids from skeletal

muscle. This response provides key nutrients to support cellular metabolism at a time when food cannot be acquired. The primary metabolic component of the acute-phase response affected by IL-6 is a qualitative alteration in hepatic protein synthesis with a resulting alteration in plasma protein composition. Characteristically, proteins acting as serum transport and binding molecules (albumin, transferrin) are reduced in quantity, and acute-phase proteins (fibrinogen, C-reactive protein) are increased. Acute-phase proteins are elaborated, in part, for the purpose of reducing the systemic effects of tissue damage. While the true physiologic role of many of the acute-phase proteins remains unclear, many act as antiproteases, opsonins, or coagulation and wound-healing factors, and they likely inhibit the generalized tissue destruction that is associated with the local initiation of inflammation. For example, increases in fibrinogen enhance thrombus formation, while antiproteases reduce tissue damage caused by proteases released by dead or dying cells. C-reactive protein has been hypothesized to have a scavenger function and its serum level can be a measure of the inflammatory response. This acute-phase response normally confers a significant survival advantage following injury and infection.

Hypoferremia and Hypozincemia. Serum iron and zinc levels are reduced in septic patients, an event that is cytokine mediated. The decrease in serum iron is probably important in protecting the host against various bacteria. The reduction of iron can inhibit the growth rate of microorganisms that have a strict requirement for iron as a growth factor. Both TNF and IL-1 have been shown to mediate hypoferremia, hypozincemia, and other alterations in trace element metabolism.

In chronic disease states, the milieu of mediators remains predominantly proinflammatory, leading to prolonged tissue damage and systemic effects on immune function, body composition, and metabolism.

Induction of the inflammatory response requires a stimulus. Physical injury and invasion of antigen are the stimuli most often described (trauma, pancreatitis, infection). However, local areas of hypoxia can be an inflammatory stimulus, so that heart failure and chronic obstructive pulmonary disease (COPD) may be added to the list of conditions that might cause inflammation.^{30,31} Conversion of self to non-self tissue (e.g., cancer) or faulty recognition of self versus nonself tissue (e.g., inflammatory bowel disease, rheumatologic conditions) can also elicit inflammation.²⁵

SPECIFIC STIMULANTS OF THE STRESS RESPONSE

Volume Loss and Tissue Hypoperfusion

Following hemorrhage or plasma loss, the body immediately attempts to compensate in order to maintain adequate organ perfusion. Pressure receptors in the aortic arch and carotid artery and volume (stretch) receptors in the wall of the left atrium detect the fall in blood volume and immediately respond by signaling the brain. Heart rate and stroke volume increase. Afferent nerve signals are also initiated, which stimulate the release of both antidiuretic hormone (ADH) and aldosterone. ADH is produced by the posterior pituitary gland in response to hypotonicity and acts to increase water reabsorption in the kidney. Aldosterone is produced via the renin-angiotensin system when the juxtaglomerular apparatus in the kidney senses a fall in pulse pressure. Aldosterone increases renal sodium reabsorption to conserve intravascular water. These mechanisms are only partially effective and, in the absence of adequate resuscitation, severe hemorrhage often leads to a prolonged low-flow state (shock). Under these circumstances, oxygen delivery is inadequate to meet tissue

demands and the cell is forced to switch to anaerobic metabolism, leading to lactic acidosis.

Tissue Damage

Injury of body tissues appears to be the most important factor setting the stress response into motion. Hypovolemia and starvation do not initiate a hypermetabolic/hypercatabolic response unless they result in infection or tissue injury. For example, prolonged underperfusion may lead to ischemia, cellular death, and the release of toxic products that can initiate the “stress” response. Afferent neural pathways from the wound signal the hypothalamus that injury has occurred; tissue destruction is generally sensed in the conscious patient as pain. Efferent pathways from the brain are immediately triggered and stimulate a number of responses designed to maintain homeostasis.

Pain and Fear

Pain and fear are established components of the stress response. Both lead to excessive production of the catecholamines preparing the body for the “fight or flight” response.

Lack of Nutrient Intake and the Consequences of Malnutrition

The metabolic response to injury and surgery demands increased energy expenditure. In many patients undergoing surgery, nutrient intake is inadequate for a period of time (1 to 5 days) following operation. If energy intake is minimal (e.g., 5% dextrose infusion), oxidation of body fat stores and erosion of lean body mass occur, with the resultant loss of weight. Body glycogen stores are limited and are depleted within 24 to 36 hours. Consequently, glucose, which is required by the central nervous system and white blood cells, must be synthesized *de novo*. Amino acids, released principally by skeletal muscle, are the major gluconeogenic precursors. Most injured patients can tolerate a loss of 15% of their preinjury weight without a significant increase in the risk of surgery. When weight loss exceeds 15% of body weight, the complications of undernutrition interact with the stress process and impair the body's ability to respond appropriately to the injury, and may impair responses to added complications such as infection.

8 The major goal of nutritional support, especially via the GI tract, in the surgical patient is to match the energy and nitrogen expenditure that occurs following injury in order to aid host defense.^{35–37} In contrast to injured patients, the catabolic and hypermetabolic responses that occur after elective operations are of a lesser magnitude because there is less tissue destruction and the neurohormonal/inflammatory response is less intense. Consequently, well-nourished patients undergoing major operations do not require nutritional support after surgery unless it is anticipated that food intake will be precluded for more than 7 days.

Invasive Infection

The major complication observed in surgical patients is infection. Most patients, particularly those in intensive care units, are exposed to a variety of infectious agents in the hospital. Normal barrier defense mechanisms are disrupted by multiple indwelling pieces of plastic such as intravenous catheters and nasotracheal and nasogastric tubes. Breakdown of skin and mucous membranes allows portals of entry for bacteria.³⁸ Infection alone may initiate catabolic responses that are similar to those described following injury in noninfected

patients. Both processes cause fever, hyperventilation, tachycardia, accelerated gluconeogenesis, increased proteolysis, and lipolysis, with fat utilized as the principal fuel source. Inflammatory cells release a variety of soluble mediators that aid host resistance and wound repair, but undernutrition may compromise the available host defense mechanisms and thereby increase the likelihood of invasive sepsis, multiple organ system failure, and death.

DETERMINANTS OF HOST RESPONSES TO SURGICAL STRESS

The pattern of physiologic changes elicited in response to surgical stress results from the specific interaction of an individual patient with the stressful stimulus. The host must be capable of transmitting and integrating injury signals, both neural and humoral, and then mounting an appropriate response that requires the interaction of a number of organ systems. The nature, intensity, and duration of the stress are fundamental determinants of both the host mediators activated and the physiologic changes observed. The responses that follow a minor elective operation are similar to those observed during a comparable, brief period of fasting and bed rest. On the other hand, major thermal injury results in a prolonged period of hypermetabolism and a severe drain on the body's energy and protein stores, resolving only with wound closure and resolution of the sepsis that may have developed. Thus, there are profound metabolic differences between the body's response to simple starvation and major stress (Table 3.6).

Body Composition

Body composition is a major determinant of the metabolic responses observed during surgical illness. Posttraumatic nitrogen excretion is directly related to the size of the body protein mass. The balance of nitrogen intake versus output from the body serves as a marker of protein metabolism. The net loss of a certain amount of nitrogen from the body implies the net breakdown of the corresponding amount of protein. In women, the size of the skeletal muscle mass is about one-half that of age-matched men; thus, it is the muscular young man in whom nitrogen losses are most marked after injury, and it is the elderly, sedentary woman in whom they are the least marked.⁸

Nutritional Status

- 9 A strong relation between protein depletion and postoperative complications has been demonstrated in nonseptic, nonimmunocompromised patients undergoing elective major gastrointestinal surgery.²³ Protein-depleted patients had significantly lower preoperative respiratory muscle strength and vital capacity, an increased incidence of postoperative pneumonia, and longer postoperative hospital stays. Impaired wound healing as well as decreased respiratory, hepatic, and muscle function in protein-depleted patients awaiting surgery have also been reported.

Age

Many of the changes in the metabolic responses to surgical illness that occur with aging can be attributed to alterations in body composition and to longstanding patterns of physical activity. Although weight remains more or less stable, fat mass tends to increase with age while muscle mass tends to decrease. The loss of strength that accompanies immobility, starvation, and acute surgical illness may have marked functional consequences. The capacity of muscle to serve as an energy source may be limited during prolonged illness in the elderly patient, and muscle strength may rapidly become inadequate for respiratory and other vital muscle function.

After the limited stress of elective operation, increases in energy expenditure are independent of age. Endocrine responses to elective operation and to trauma appear intact in older patients in terms of plasma cortisol levels and urinary excretion of adrenaline, noradrenaline, and 17-hydroxycorticosteroids.

The prevalence of cardiovascular and pulmonary diseases increases with age. Diminished arterial compliance, impaired vasoconstriction, altered autonomic function and sensitivity to catecholamines, and decreased baroreflex sensitivity may all impair the maintenance of cardiovascular homeostasis during acute surgical illness. Thus, the delivery of oxygen to the tissues may be impaired in the elderly and may be inadequate when oxygen demands are highest.

Gender

Observed differences between the metabolic responses of men and women in general reflect differences in body composition. Lean body mass, expressed as a proportion of body weight, is

TABLE 3.6

METABOLIC DIFFERENCES BETWEEN THE RESPONSE TO SIMPLE STARVATION AND TO INJURY

	■ SIMPLE STARVATION	■ SEVERE INJURY
Basal metabolic rate	—	++
Presence of mediators	—	+++
Major fuel oxidized	Fat	Mixed
Ketone body production	+++	±
Hepatic ureagenesis	+	+++
Negative nitrogen balance	+	+++
Gluconeogenesis	+	+++
Muscle proteolysis	+	+++
Hepatic protein synthesis	+	+++

lower in women than in men; this difference is thought to account for the lower net loss of nitrogen after major elective abdominal surgery in women.

The Gut Mucosal Barrier Dysfunction as a Mediator of the Stress Response

10 Under certain circumstances, the gut may become a source of sepsis and serve as the motor of the systemic inflammatory response syndrome. The maintenance of an intact brush border and intercellular tight junctions prevents the movement of toxic substances into the intestinal lymphatics and circulation; these functions may become altered in critically ill patients. Maintenance of a gut mucosal barrier that effectively excludes luminal bacteria and toxins requires normal perfusion, an intact epithelium, and normal mucosal immune mechanisms.

Microbial translocation is the process by which microorganisms migrate across the mucosal barrier and invade the host.³⁷ Translocation can be promoted in three general ways: (a) altered permeability of the intestinal mucosa, (b) decreased host defense, and (c) an increased number of bacteria within the intestine. Hemorrhagic shock, hypoxemia, sepsis, distant injury, or administration of cell toxins leads to altered permeability. Glucocorticoid administration, immunosuppression, or protein depletion decreases host defense. Bacterial overgrowth in association with intestinal stasis may cause translocation.

Even if actual migration of whole bacteria does not occur, the gut may absorb endotoxin into the portal venous system. A number of retrospective and epidemiologic studies have associated infection in specific patient populations with bacterial invasion from the gut. These studies have demonstrated an increase in mucosal permeability both in normal volunteers who received endotoxin and in infected burn patients. Because many of the factors that facilitate bacterial translocation occur simultaneously in surgical patients and their effects may be additive or cumulative, patients in an intensive care unit may be extremely vulnerable to the invasion of enteric bacteria or to the absorption of their toxins. Such patients do not generally receive enteral feedings and current parenteral therapy results in gut atrophy. Methods currently used to support critically ill patients neither facilitate repair of the intestinal mucosa nor maintain gut barrier function. Provision of early enteral feeds and glutamine do the most to prevent translocation.

Elective Operations and Physiologic Responses to Surgery

The physiologic responses to surgical stress are multiple and complex (Fig. 3.7). One of the earliest consequences of a surgical procedure is the rise in levels of circulating cortisol occurring in response to a sudden outpouring of adrenocorticotrophic hormone (ACTH) from the anterior pituitary gland.

FIGURE 3.7. Homeostatic adjustments initiated after injury.

The rise in ACTH stimulates the adrenal cortex to elaborate cortisol, which remains elevated for 24 to 48 hours after operation. Cortisol has generalized effects on tissue catabolism and mobilizes amino acids from skeletal muscle that provide substrates for wound healing and serve as precursors for the hepatic synthesis of acute-phase proteins or new glucose. Associated with the activation of the adrenal cortex is stimulation of the adrenal medulla through the sympathetic nervous system, with elaboration of epinephrine and norepinephrine. These circulating neurotransmitters play an important role in circulatory adjustment, but may also elicit metabolic responses if the augmented secretion rate continues over a prolonged period of time.

The neuroendocrine responses to operation also modify the various mechanisms that regulate salt and water excretion. Alterations in serum osmolarity and tonicity of body fluids secondary to anesthesia and operative stress stimulate the secretion of aldosterone and ADH. Aldosterone is a potent stimulator of renal sodium retention, whereas ADH stimulates renal tubular water reabsorption. Thus, the ability to excrete a water load after elective surgical procedures is restricted and weight gain secondary to salt and water retention is usual following operation. Edema occurs to a varying extent in all surgical wounds, and this accumulation is proportional to the extent of tissue dissection and local trauma. This “third-spaced” fluid eventually returns to the circulation as the wound edema subsides and diuresis commences 2 to 4 days following the operation.

Alterations occur in the response of the endocrine pancreas following elective operation. In general, insulin elaboration is diminished, and glucagon concentrations rise. This response may be related to increased sympathetic activity or to the rise in levels of circulating epinephrine known to suppress insulin release. The rise in glucagon and the corresponding fall in insulin are a potent signal to accelerate hepatic glucose production, and, with the help of other hormones (epinephrine and glucocorticoids), gluconeogenesis is maintained.

The period of catabolism initiated by operation characterized by a combination of inadequate nutrition and alteration of the hormonal environment has been termed the “adrenergic-corticoid phase.” This phase generally lasts 1 to 3 days and is followed by the “adrenergic-corticoid withdrawal phase,” which lasts 1 to 3 days. This period is followed by the onset of anabolism, which occurs at a variable time in the patient’s convalescence. In general, in the absence of postoperative complications, this phase starts 3 to 6 days after an abdominal operation of the magnitude of a colectomy or gastrectomy, often concomitant with the commencement of oral feedings. The patient then enters a prolonged period of early anabolism characterized by positive nitrogen balance and weight gain. Protein synthesis is increased as a result of sustained enteral feedings, and this change is related to the return of lean body mass and muscular strength.

SEPSIS: GENERAL OVERVIEW AND TIME COURSE OF THE METABOLIC RESPONSE TO SEPSIS

The response patterns following major infection are less predictable than those following elective operations and trauma. The invasion of the body by microorganisms initiates many host responses including mobilization of phagocytes, an inflammatory response at the local site, fever, tachycardia, and other systemic responses. Systemic events during the hyperdynamic phase of sepsis can be categorized into two general types of responses: (a) those related to the host’s immunologic defenses and (b) those related to the body’s general metabolic and circulatory adjustments to the infection. The changes in metabolism relate to alterations in glucose, nitrogen, and fat metabolism, as well as the redistribution of trace metals.

Systemic Metabolic Responses

Severe infection is characterized by fever, hypermetabolism, diminished protein economy, altered glucose dynamics, and accelerated lipolysis, much like the injured patient. Anorexia is commonly associated with systemic infection and contributes to the loss of lean body tissue. These effects are compounded in the patient with sepsis by multiorgan system failure, which includes the gastrointestinal tract, liver, heart, and lungs.

Hypermetabolism. Oxygen consumption is usually elevated in the infected patient. The extent of this increase is related to the severity of infection, with peak elevations reaching 50% to 60% above normal. Such responses often occur in the postoperative and postinjury periods secondary to severe pneumonia, intra-abdominal infection, or wound invasion. If the patient’s metabolic rate is already elevated to a maximal extent because of severe injury, no further increase occurs. In patients with only slightly accelerated rates of oxygen consumption, the presence of infection causes a rise in metabolic rate that appears additive to the preexisting state. A portion of the increase in metabolism may be ascribed to the increase in reaction rate associated with fever (Q10 effect). Calculations suggest that the metabolic rate increases 10% to 13% for each elevation of 1°C in central temperature. On resolution of the infection, the metabolic rate returns to normal.

Altered Glucose Dynamics. The observation that glucose production is increased in infected patients appears to be additive to the augmented gluconeogenesis that occurs following injury. For example, uninfected burn patients have an accelerated glucose production rate approximately 50% above normal; with the onset of bacteremia in similar individuals, hepatic glucose production increases to twice basal levels. Glucose dynamics following infection are complex, and profound hypoglycemia and diminished hepatic glucose production have also been described in both animals and human patients. Studies in animals and in human patients show that deterioration in gluconeogenesis is associated with more progressive stages of infection and may be related to alterations in splanchnic blood flow.

Alterations in Protein Metabolism. Accelerated proteolysis, increased nitrogen excretion, and prolonged negative nitrogen balance occur following infection, and the response pattern is similar to that described for injury. Amino acid efflux from skeletal muscle is accelerated in patients with sepsis, and this flux is matched by accelerated visceral amino acid uptake. In infected burn patients, splanchnic uptake of amino acids is increased 50% above rates in uninfected burn patients with injuries of comparable size. These amino acids serve as glucose precursors and are used for synthesis of acute-phase proteins. Studies in animals have demonstrated that an increase in hepatic amino acid uptake during systemic infection is due to an increase in the activities of specific amino acid transporters that reside in the hepatocyte plasma membrane.

Severe infection is often associated with a hypercatabolic state that initiates marked changes in interorgan glutamine metabolism (Fig. 3.8). The cycle may begin with a breakdown in the gut mucosal barrier resulting in microbial translocation. Bacteria and their endotoxins stimulate macrophages to release cytokines, which activate the pituitary/adrenal axis. The release of cortisol stimulates glutamine synthesis and release by tissues such as the lungs and skeletal muscle. The bulk of the glutamine is taken up by the liver at the expense of the gut. Acidosis frequently occurs in the patient with sepsis, and this stimulus serves as a signal for accelerated glutamine uptake by the kidney. Glutamine liberates an ammonia ion that combines with a hydrogen ion and is excreted in the urine, thus participating in acid-base homeostasis. Because the glutamine arises from skeletal muscle proteolysis, this complication of sepsis is yet another stimulus of heightened skeletal muscle breakdown.

FIGURE 3.8. The interorgan glutamine cycle can be initiated by any local and/or systemic catabolic insult that redirects the flow of glutamine and results in glutamine depletion. In the case illustrated here, the patient develops a breakdown in the gut mucosal barrier, which causes an increase in bowel permeability and bacterial translocation. Bacteria and endotoxins stimulate macrophages to release cytokines (tumor necrosis factor [TNF], interleukin-1 [IL-1], IL-6), which exert direct effects on glutamine metabolism in various organs and also stimulate release of the counterregulatory hormones. These mediators work together to mobilize glutamine stores from muscle and to stimulate glutamine production by the lungs. A central goal is to support the increased glutamine requirements in other tissues. It is unclear why organs such as the gut should subserve other tissues, but it is apparent that if the cycle persists, or if the patient is unable to take oral feedings or remains glutamine deficient, a prolonged catabolic state develops.

Alterations in Fat Metabolism. Fat is a major fuel oxidized in infected patients, and the increased metabolism of lipids from peripheral fat stores is especially prominent during a period of inadequate nutritional support. Lipolysis is most probably mediated by the heightened sympathetic activity that is a potent stimulus for fat mobilization and accelerated oxidation. Serum triglyceride levels reflect the balance between rates of triglyceride production by the liver and use and storage by peripheral tissues. Marked hypertriglyceridemia has been associated with gram-negative infection on occasion, but plasma triglyceride concentrations are usually normal or low, indicating enhanced clearance by other organs. Infected patients cannot convert fatty acids to ketones efficiently in the liver, and hence do not adapt to starvation like fasted, unstressed individuals. It has been suggested that the low ketone levels of infection may be a consequence of the hyperinsulinemia associated with catabolic states.

Changes in Trace Mineral Metabolism. Changes in balance of magnesium, inorganic phosphate, zinc, and potassium generally follow alterations in nitrogen balance. Although the iron-binding capacity of transferrin is usually unchanged in early infection, iron disappears from the plasma, especially during severe pyrogenic infections; similar alterations are observed with serum zinc levels. These decreases cannot be totally accounted for by losses of the minerals from the body. Rather, both iron and zinc accumulate within the liver, and this accumulation appears to be another host defense mechanism. The administration of iron to the infected host, especially early in the disease, is contraindicated because increased serum iron concentrations may impair resistance. Unlike iron and zinc, copper levels generally rise, and the increased plasma concentrations can be ascribed almost entirely to the increase in ceruloplasmin produced by the liver.

Nutritional Requirements and Special Feeding Problems

As with all patients, the primary objectives of nutritional assessment are to evaluate the patient's present nutritional status and to determine energy, protein, and macro- and micronutrient requirements. Weight gain and anabolism are generally difficult to achieve during the septic process, but they do occur once the disease process has abated. Total energy requirements can be calculated using the stress equation; mild to moderate infections increase energy requirements 20% to 30%, and severe infection with fever increases caloric needs ~50% above basal levels. The most severe complication of sepsis is the multiple organ dysfunction syndrome, which may result in death. The current treatment of systemic infection consists of (a) removal or drainage of the septic source; (b) use of appropriate antibiotics; (c) supportive therapy of specific organ failure, whether cardiac, pulmonary, hepatic, renal, or gastrointestinal; and (d) vigorous support of the host through nutritional means.

Respiratory Insufficiency. A common problem associated with systemic infection is oxygenation and elimination of carbon dioxide in patients with a compromised pulmonary status. Patients often require intubation and vigorous ventilatory support, and hypermetabolism is a common feature of their illness. Hypermetabolism is accompanied by increased oxygen consumption, which drives carbon dioxide production as more substrate must be oxidized to support the hypermetabolic response. Within this model, composition of diet (carbohydrate vs. fat) is relatively unimportant in determining the carbon dioxide burden (carbohydrate at respiratory quotient [RQ] 1.0 releasing more CO₂ than fat at RQ 0.7). Avoidance of overfeeding is the primary concern in

reducing the nutritional contribution to CO₂ production. Only in the most severely compromised patients does the change in CO₂ production from diet composition make a difference. The decision to reduce carbohydrate intake and increase lipid intake must be weighed carefully because high-fat diets, especially fats high in n-6 fatty acids, may exacerbate lung injury.

Renal Failure

Renal failure significantly compromises the body's ability to clear the byproducts of protein metabolism, but does not reduce the catabolic rate or the need for dietary protein. A nexus therefore exists between nutrition and renal management: should protein intake be determined by the protein needs of the patient or by a desire to limit uremia and the need for dialysis? Under such conditions, it is important not only to avoid overfeeding protein, but also to be aggressive with dialytic therapy so that protein is not restricted to less than the body's requirement. Careful assessment of protein-calorie needs is critical.

Gut Dysfunction. Sepsis causes marked changes in gastrointestinal function. The most common abnormality is ileus, which can result from intra-abdominal disease or from the effects of bacteria elsewhere. Breakdown of the gut mucosal barrier with translocation of luminal bacteria and their toxins can initiate a prolonged hypermetabolic state.

Hepatic Failure. Hepatic dysfunction is a common manifestation of septicemia. The degree of dysfunction is variable and may appear early as a slight elevation of liver enzymes, or it may cause severe jaundice and hyperbilirubinemia. Hepatic dysfunction generally resolves on resolution of the sepsis, but if the inflammatory process persists, adjustments in the feeding formulation are necessary. Balanced carbohydrate and fat intake are important with avoidance of overfeeding. The patient should be observed for the presence of encephalopathy; if this complication occurs and cannot be controlled by lactulose usage, then the protein load should also be reduced. Another indicator for limiting protein to less than 1.5 g/kg body weight is an elevated prothrombin time, as this indicates impairment of hepatic protein synthetic function. Of course, vitamin K and anticoagulants must be eliminated as causes of the change.

Cardiac Dysfunction. The myocardial dysfunction that occurs in sepsis may be secondary to the elaboration of cytokines such as TNF or IL-1, which have direct myocardial depressant activity. Alternatively, the heart failure may be secondary to pulmonary insufficiency with an increased pulmonary vascular resistance and right ventricular overload. Malnourished patients with sepsis may be sensitive to volume overload, and use of a concentrated enteral or parenteral feeding solution may be indicated to maximize calories and to minimize volume.

CANCER AND ACQUIRED IMMUNODEFICIENCY SYNDROME

- 11** Nutrition support of patients with cancer or acquired immunodeficiency syndrome (AIDS), whose inflammatory states are very similar, needs to be directed at two major areas: (a) providing nutrition when symptoms of the disease or side effects of treatment prevent adequate intake and (b) fighting the inflammatory state created by the disease.

Cancers of the aerodigestive tract interfere with swallowing and/or digestion, precluding adequate caloric or protein intake. Dysgeusia (altered taste perception) may also prevent adequate intake, as may mouth sores and irritation of the pharynx and esophagus from chemotherapy, fungal infections, and radiation. Careful attention to a patient's symptoms and provision of zinc and B vitamins may help with taste. Soft foods, slushies, or slurries may help patients get better intake through an irritated or partially obstructed throat or esophagus. Treatment of nausea and constipation allows more interest in food.

Cancer cachexia occurs with many tumors and especially aggressive ones. The later stages of AIDS have a cachexia just like cancer. The cachectic state is just a chronic inflammatory state that cannot be reversed even with adequate calories and protein. Proinflammatory cytokines (TNF, IL-1, IL-6) are constantly released in response to the tumor and lead to a chronic state of muscle wasting and fat loss. Only a reversal of the inflammatory response can ameliorate the cachexia.

- 12** Cancer or AIDS cachexia cannot be cured, only managed, and so removing the stimulus for inflammation is not possible. Instead, inflammation might be managed by provision of substances that interrupt or modify the inflammatory cascade to orient it in the anti-inflammatory direction. Pharmacologic options for interruption of inflammation include several of the nonsteroidal anti-inflammatory drugs (including celecoxib) and anticytokine medications. The nutritional strategies range from regular foods to functional foods to food supplements.

Among the most promising nutritional agents for promoting an anti-inflammatory milieu is the balance of n-6 to n-3 fatty acids in the body.³⁸ The source of these fatty acids is the diet, and dietary fatty acids are quickly incorporated into cell membranes, influencing the membranes' characteristics and function. These fatty acids are also the raw material for eicosanoid production.³⁹ The type of eicosanoid produced depends on the types of fatty acids contained in the cell membranes. The dietary and intravenous n-6 fatty acid is linoleic acid, which is incorporated into cell membranes as arachidonic acid, which gives rise to proinflammatory PG₂ and LT₄. The dietary n-3 fatty acids are α -linolenic, eicosapentaenoic, and docosahexaenoic acid and are incorporated into cell membranes as the more anti-inflammatory PG₃ and LT₅. These anti-inflammatory eicosanoids interrupt the release of IL-6, thus potentially allowing IGF-1 levels to normalize in the patient with cachexia.⁴⁰ The typical modern Western diet is high in the ratio of n-6 to n-3 fatty acids (about 15:1). A more therapeutic ratio would be 2:1 to 4:1. In managing cachexia, the nutritional recommendation is to increase calorie and protein intake by any means possible. This often means dairy foods and protein sources from cold-water fish, which tend to keep the n-3 level high.

In three studies, pancreatic cancer patients consumed 3 g of eicosapentaenoic acid (EPA), a marine source of n-3 fatty acid, in a calorie/protein liquid supplement.⁴¹⁻⁴³ By doing so, patients gained weight (as fat-free mass, an indicator of anabolism); increased their grip strength; reduced their levels of C-reactive protein, IL-6, and resting metabolic rate (markers of decreased inflammation); and improved their scores on quality-of-life and functional status questionnaires. In another randomized trial, daily supplementation of 18 g n-3 fatty acid improved survival time in malnourished patients with solid tumors.⁴⁴

Another possible nutritional intervention in cachexia of chronic illness is amino acid supplementation, specifically arginine, glutamine, and/or branched chain amino acids (leucine, isoleucine, valine). It should be remembered that the metabolic pathways of all of these amino acids intersect in human metabolism, so supplementation with all of them may not be required. Be that as it may, two double-blind, randomized clinical trials of a commercially available amino acid supplement

containing 14 g arginine, 14 g glutamine, and 3 g β -hydroxy- β -methylbutyrate (an analog of leucine) has shown that such supplementation can increase the fat-free mass of cachectic cancer patients (stage IV solid tumors) and patients with stage III AIDS.^{45,46}

OTHER METHODS OF MODIFYING THE CATABOLIC RESPONSE TO SURGERY AND CRITICAL ILLNESS

Besides nutritional intervention, other methods to modify the physiologic and biochemical response to operation have been studied in an effort to reduce the magnitude of the stress response and to provide insight into possible mechanisms. Regional anesthetic techniques block afferent signals from the wound and interrupt sympathetic nervous efferent signals to the adrenal gland and possibly the liver, reducing the apparent magnitude of the stress response. Others have studied stress responses in sympathectomized animals by blocking the efferent limb of the neuroendocrine reflex response. These reports indicate that central nervous system blockade interrupts afferent signals stimulated by operative procedures.

More recent studies have documented the safety and efficacy of long-term exogenous recombinant growth hormone (GH) administration.⁴⁷ GH stimulates protein synthesis during hypocaloric feedings and increases retention of sodium and potassium by the kidney. The potential synergistic effects of specialized nutrition in combination with GH require further study. Cyclooxygenase inhibitors such as aspirin and ibuprofen attenuate the symptoms and endocrine responses that occur with critical illness without altering cytokine elaboration. It is anticipated that researchers may eventually be able to selectively block the deleterious effects of excessive cytokines yet preserve their beneficial effects.

Research Findings

One of the difficulties in applying the research on nutritional modulation of the inflammatory response is that research protocols target particular diseases, and so results are often not generalizable (i.e., a study that shows an improvement in body composition and quality of life in cancer patients cannot be generalized to patients with congestive heart failure).

Although novel approaches to the management of the inflammatory response are becoming clinical realities,⁴⁸ the current standard of supplemental macro- and micronutrients should not be ignored. Akner and Cederholm²³ reviewed the literature and found that in 60% of 36 randomized controlled trials, standard supplementation of nutrient intake improved function/morbidity, and in 80% of 41 randomized controlled trials, standard supplementation improved anthropometric variables. However, this leaves a large percentage of studies in which standard support of calorie, protein, and micronutrient intake did not have a positive effect. The intriguing question is whether in these negative studies a more targeted form of nutrition support would have had the desired effect.

CHOICE OF NUTRITION IN SURGICAL PATIENTS: ENTERAL OR PARENTERAL?

Although the physiologic advantage of enteral nutrition is apparent, preoperative nutritional repletion via the enteral

route has not been as extensively studied as preoperative total parenteral nutrition (TPN). Although its use can be associated with the development of nausea, diarrhea, and distention, we recommend the use of enteral nutrition (via a feeding tube or as in-between-meal supplements) in malnourished patients if it is feasible. Candidates must have a functional GI tract and must be able to receive adequate amounts of calories and nitrogen. In many critically ill patients, enteral nutrition-related gastrointestinal complications are high and associated with decreased nutrient intake from the ordered levels.^{49,50} Furthermore, forcing the enteral issue in patients who are intolerant of enteral nutrition is more detrimental than properly managed parenteral nutrition.

NUTRITION AS PRIMARY THERAPY

1. Patients with enterocutaneous fistulas (parenteral preferred but enteral could be used with a low-output fistula)

Patients with gastrointestinal-cutaneous fistulas represent the classic indication for TPN. In such patients, oral intake of food almost invariably results in increased fistula output, which can lead to metabolic disturbances, dehydration, and death. Several comprehensive reviews have concluded that total parenteral nutrition clearly impacts the treatment and course of disease for patients with GI fistulas. The following conclusions can be drawn from studies evaluating the use of TPN in patients with enterocutaneous fistulas: (a) TPN increases the spontaneous closure rate of enterocutaneous fistulas, but does not markedly decrease the mortality rate in patients with fistulas (improvements in mortality are mainly due to improved surgical and metabolic care); (b) if spontaneous closure of the fistula does not occur, patients are better prepared for operative intervention because of the nutritional support they received; and (c) certain fistulas (radiated bowel) are associated with a higher failure rate of closure than others and should be treated more aggressively surgically after a defined period of nutritional support (unless closure occurs).

2. Patients with short bowel syndrome (parenteral)

Prospective randomized trials designed specifically to examine the impact of TPN on patients with short bowel syndrome have not been initiated, mainly because such patients have no choice but to receive TPN. Most of these patients, who would have certainly died prior to the availability of TPN, now survive for long periods of time on home parenteral nutrition. In selected patients with residual small intestine (at least 18 inches), postresectional hyperplasia may develop with time such that they can tolerate enteral feedings. Studies by Wilmore and colleagues³⁹ have demonstrated that the requirement for TPN could be decreased or even eliminated in patients with short gut syndrome by providing a nutritional regimen consisting of supplemental glutamine, growth hormone, and a modified high-carbohydrate, low-fat diet. There was a marked improvement in the absorption of nutrients with this combination therapy and a decrease in stool output. In addition, TPN requirements were reduced by 50%, as were the costs associated with care of these individuals. Discontinuation of the growth hormone did not increase TPN needs in these patients once they had undergone successful gut rehabilitation.

3. Patients with hepatic failure (enteral preferred)

Individuals with liver disease may be malnourished because of excessive alcohol intake, diminished food intake, or an inflammatory state from viral infection. These individuals are protein depleted yet are intolerant of protein because of their tendency to become encephalopathic with a high nitrogen intake.

Because of liver damage and portasystemic shunting, these patients develop derangements in circulating levels of amino acids. The plasma aromatic-to-branched chain amino acid ratio is increased, favoring the transport of aromatic amino acids across the blood-brain barrier. These amino acids are precursors of false neurotransmitters that contribute to lethargy and encephalopathy. Treatment of individuals with liver failure with solutions enriched in branched chain amino acids and deficient in aromatic amino acids results in improved tolerance to the administered protein and clinical improvement in the encephalopathic state.

4. Patients with major thermal injury (enteral preferred if possible)

Aggressive nutritional support in patients with major burns seems to be associated with improved survival, particularly when increased amounts of dietary protein are provided.⁵¹ Burned patients often require ventilatory support and/or suffer from ileus, which prevents using the GI tract for feeding. Even if the GI tract is usable, such patients are often unable to eat enough because of frequent trips to the operating room combined with the anorexia of severe injury. Most burn authorities believe that aggressive nutritional support in patients with major thermal injury has influenced outcome in a positive manner.

5. Patients with acute renal failure (enteral preferred if possible)

TPN with amino acids of high biologic value *may* decrease the mortality in patients with acute renal failure.⁵² The use of solutions containing high-quality amino acids can improve nitrogen balance and diminish urea production. This translates into a decreased frequency of dialysis.

Total Parenteral Nutrition as Secondary Therapy

1. Prolonged ileus after operative procedure

Occasionally, patients develop a prolonged ileus after an abdominal procedure, which precludes the use of the intestinal tract as a route of feeding. Such an occurrence is generally unpredictable and the cause of the ileus is often not demonstrated. If the patient is unable to eat by the seventh postoperative day, TPN should be started. The ileus may persist for several weeks. Although provision of TPN does not influence the disease process *per se*, it is beneficial because it prevents further erosion of lean body mass.

2. Acute radiation and chemotherapy enteritis

Malnourished patients who receive abdominal or pelvic radiation or chemotherapy may develop mucositis and enterocolitis that precludes using the GI tract for prolonged periods of time. In such individuals, TPN should be provided until the enteritis resolves and oral feeding can be resumed.

3. Preoperative TPN in the perioperative setting

In general, one cannot justify the use of perioperative nutrition (particularly parenteral feedings) unless a clear benefit to the patient can be demonstrated. The results of prospective randomized trials evaluating the efficacy of preoperative TPN are conflicting because of the variations in the nutritional status of patients studied, the differences in types of diseases in these malnourished patients, the differences in the type and length of nutritional support administered, and the failure to accrue enough patients to avoid type II statistical error. The following questions are important to consider: Does preoperative nutritional support decrease the morbidity and mortality associated with major operative procedures? How long should nutritional support be administered? What type of nutritional repletion should be administered?

One of the best studies to date evaluating the efficacy of preoperative TPN was published by the Veterans Affairs Total Parenteral Nutrition Cooperative Study Group.⁵³ More than 3,500 patients requiring mainly elective abdominal surgery were entered into this prospective randomized trial. They were initially screened for evidence of malnutrition using subjective criteria and/or by determining their Nutritional Risk Index Score, which included objective criteria such as percentage of weight loss and serum albumin level. The patients were further divided into categories assigning them to one of four groups: well nourished, borderline malnourished, moderately malnourished, or severely malnourished. Patients in each malnourished category were randomized to receive at least 7 days of preoperative TPN or to proceed with surgery without preoperative TPN. Patients randomized to receive TPN received 1,000 kcal/day in excess of calculated caloric requirements. Lipid was provided on a daily basis. One criticism of this study was that patients were allowed to eat in addition to receiving parenteral feedings.

Analysis of the data from this study indicated that there was no difference in short-term or long-term complications between groups. Infectious complications including pneumonia, abscess, and line sepsis were statistically significantly higher for patients receiving TPN.⁵⁴ Noninfectious complications (impaired wound healing) were significantly lower only in those patients receiving TPN who were in the severely malnourished group (>15% weight loss and serum albumin <2.9 mg). This study strongly suggests that preoperative TPN should be provided only to severely malnourished patients who cannot be nourished by the enteral route. Contraindications to the use of preoperative TPN include patients requiring emergency operation and those who are only mildly or moderately malnourished. In such patients, TPN should be continued postoperatively only if the GI tract cannot be utilized for tube feedings. Nasojejunal or jejunostomy tubes should also be considered in patients undergoing major upper abdominal procedures in whom it is anticipated that oral feedings may not be resumed for 7 to 10 days after surgery.

Composition of Total Parenteral Nutrition Formulations

Total parenteral nutrition solutions are administered through a central venous catheter generally inserted into the subclavian vein (Fig. 3.9). The composition of a standard TPN solution is shown in Table 3.7. Because of the hyperosmolality of such solutions, they must be delivered into a high-flow system to prevent venous sclerosis. Patients receiving TPN should be monitored regularly by measuring blood sugar, serum electrolytes, and liver function tests. Elevations in serum glucose are common in surgical patients receiving TPN, especially if the patient is stressed and is relatively glucose intolerant. Hyperglycemia can generally be controlled by adding insulin to the TPN formulation or by decreasing the amount of glucose in the solution. It has been shown that injured people can maximally oxidize about 4 to 5 mg of glucose/kg/min. For a 70-kg man, this is equal to approximately 400 to 500 g/day (1,600 to 2,000 kcal/day). Excess glucose calories are converted to fat, are deposited in the liver, and result in hyperglycemia and glycosuria. Glycosuria with its osmotic load leads to a water diuresis that leaves the patient with a hyperosmolar state that can progress to coma as the brain is depleted of water. The amounts of the various electrolytes provided to patients receiving TPN vary depending on factors such as previous nutritional and hydration status. Careful monitoring is critical because as new cell mass is built, potassium and phosphate can move into cells, leading to severe hypokalemia or hypophosphatemia. These electrolyte disturbances can develop rapidly and are much more life threatening than hyponatremia. Vitamin (Table 3.8) and trace mineral (Table 3.9) requirements must also be monitored.

TABLE 3.7**COMPOSITION OF A STANDARD CENTRAL VENOUS SOLUTION**

Volume	10% Amino acid solution	500 mL
	50% Dextrose solution	500 mL
	Fat emulsion	—
	Electrolytes + vitamins + minerals	~50 mL
	Total volume	~1,050 mL
Composition	Amino acids	50 g
	Dextrose	250 g
	Total N	$50/6.25 = 8 \text{ g}$
	Dextrose kcal	$250 \text{ g} \times 3.4 \text{ kcal/g} = 840 \text{ kcal}$
	mOsm/L	~2,000
Electrolytes Added to Total Parenteral Nutrition Solutions		
	Usual concentration	Range of concentrations
Sodium (mEq/L)	60	0–150
Potassium (mEq/L)	40	0–80
Acetate (mEq/L)	50	50–150
Chloride (mEq/L)	50	0–150

The use of lipids in TPN was developed to meet the requirement for essential fatty acids (linoleic acid) and the full caloric needs in hypermetabolic patients, recognizing the complications associated with infusing large amounts of dextrose. Intravenous fat emulsions are composed of soy or safflower oils (vegetable fat emulsions), which contain primarily long-chain triglycerides (LCTs) composed of fatty acids with 16- and 18-carbon chain lengths. The provision of fat provides essential linoleic acid, inhibits lipogenesis from carbohydrates, and lowers the RQ, which may benefit patients with respiratory compromise. However, the high content of n-6 polyunsaturated fatty acids (in particular, linoleic acid) in these emulsions may have harmful effects on pulmonary and immune function.⁵⁵ Standard intravenous fat emulsions may alter the cell membrane phospholipid composition of cells of the reticuloendothelial system, resulting in changes in membrane fluidity such that clearance of bacteria and toxins is impaired. In addition, n-6 polyunsaturated fatty acids may alter the local production of eicosanoids and cytokines such that chemotaxis is negatively impacted. Newer nutritional methods of modifying the catabolic response to injury and infection propose the use of the n-3 fatty acids, which may decrease eicosanoid biosynthesis and thereby diminish the vasoconstriction, platelet aggregation, and immunosuppression that may occur when n-6 derivatives are administered. Studies suggest that n-3 fatty acids may be of benefit to the critically ill patient. Omega-3 fatty acids have been added to enteral formulas, but are not in parenteral formulas available in the United States.

Fat is an important fuel source for critically ill patients. Septic and injured patients preferentially utilize endogenous fat as an energy source, which appears to be related in part to the effects of counterregulatory hormones on stimulating fat mobilization. These patients have a relative unresponsiveness to the administration of carbohydrates in that free fatty acid mobilization is only marginally decreased and free fatty acid oxidation is not suppressed, as in “pure starvation.” Glucose infusion above energy expenditure in a hormonal milieu that favors fat mobilization and oxidation only leads to hepatic steatosis.

Potential Complications of Total Parenteral Nutrition

Advances in technology, monitoring, and catheter care have greatly reduced the incidence of complications associated with the use of TPN. The establishment of a nutrition support team (physician, dietician, nurse, pharmacist) and the recognition of such a team as an important part of overall patient care have also been key factors in reducing complications. Complica-

tions of TPN occur and can be divided into three types: mechanical, metabolic, and infectious (Table 3.10). The management of the patient who becomes septic while receiving TPN is shown in Algorithm 3.1.

The Effects of Total Parenteral Nutrition on the Gastrointestinal Tract

The majority of studies that have examined the effects of TPN on intestinal function and immunity have been done in animals. These studies clearly demonstrate that TPN has a downside, which is related to intestinal disuse. A unique feature of TPN is that subjects can remain on bowel rest for prolonged periods of time without concomitant malnutrition, thereby facilitating the study of intestinal disuse as an independent variable. In rats, TPN results in significant disruption of the intestinal microflora and bacterial translocation from the gut lumen to the mesenteric lymph nodes. In addition, when stresses such as burn injury, chemotherapy, or radiation are introduced in these models, animals on TPN have a much higher mortality. This body of literature suggests that TPN, under certain circumstances, may predispose patients to an increase in gut-derived infectious complications.³⁸

A provocative study in human volunteers demonstrated that individuals receiving TPN had an accentuated systemic response to endotoxin challenge compared to enterally fed volunteers.⁴⁸ The study is consistent with an impairment in gut barrier function during parenteral feedings, which may promote the release of bacteria and/or cytokines, leading to pronounced systemic responses and possibly multiple organ failure.

Supporting the Gut in Critically Ill Patients

The intestinal tract has long been considered an organ of inactivity following operation or injury. Ileus is generally present, nasogastric decompression is often necessary, and the gut is usually dormant in the immediate postoperative period. In the past, digestion and absorption was thought to be the only physiologic role of the gut. Disuse of the GI tract, either via starvation or nutritional support by TPN, may lead to numerous physiologic derangements as well as changes in gut microflora, impaired gut immune function, and disruption of the integrity of the mucosal barrier. Thus, maintaining gut function in the perioperative period may be essential in order to minimize septic complications and organ failure.

Treatment strategies designed to support the gut during critical illness should be directed toward the provision of

TABLE 3.10**COMPLICATIONS ASSOCIATED WITH THE USE OF TPN**

■ COMPLICATION	■ CAUSE	■ TREATMENT
MECHANICAL		
Pneumothorax	Puncture/laceration of lung pleura	Serial CXRs; chest tube if indicated
Subclavian artery injury	Penetration of subclavian artery during needle stick	CXR; serial monitoring of vital signs
Air embolism	Aspiration of air into the subclavian vein and right heart	Place patient in Trendelenburg and left lateral decubitus; aspirate air
Catheter embolization	Shearing off the tip when withdrawing catheter	Retrieve catheter transvenously under fluoroscopic guidance
Venous thrombosis	Clot formation in great vein secondary to catheter	Heparinization if clinically significant
Catheter malposition	Tip of catheter directed into IJ or opposite subclavian	Reposition under fluoroscopy
METABOLIC		
Hyperglycemia	Excessive glucose calories or glucose intolerance	Decrease glucose calories; administer insulin
Hypoglycemia	Sudden cessation of TPN	Bolus 50% glucose solution; monitor blood glucose
Carbon dioxide retention	Infusion of glucose calories in excess of energy needs	Decrease glucose calories and replace with fat
Hyperglycemic, hyperosmolar nonketotic coma (HHNC)	Dehydration from excessive diuresis	Discontinue TPN immediately; give insulin; monitor glucose/electrolytes
Hyperchloremic metabolic acidosis	Excessive chloride administration	Give Na and K as acetate salts
Azotemia	Excessive amino acid administration with inadequate calories	Decrease amino acids; increase glucose calories
Essential fatty acid deficiency	Inadequate essential fatty acid administration	Administer fat solution
Hypertriglyceridemia	Rapid fat infusion of decreased fat clearance	Slow rate of fat infusion
Hypophosphatemia	Inadequate administration of electrolyte in question	Increase administration
Hypocalcemia		
Hypomagnesemia		
Hypokalemia		
Bleeding	Vitamin K deficiency	Administer Vitamin K
SEPTIC		
Line sepsis	Catheter tip infected	Remove catheter; antibiotics
Infection at skin site	Bacteria at site of catheter entry into skin	Remove catheter; local wound care

CXR, chest radiograph; IJ, internal jugular; TPN, total parenteral nutrition.

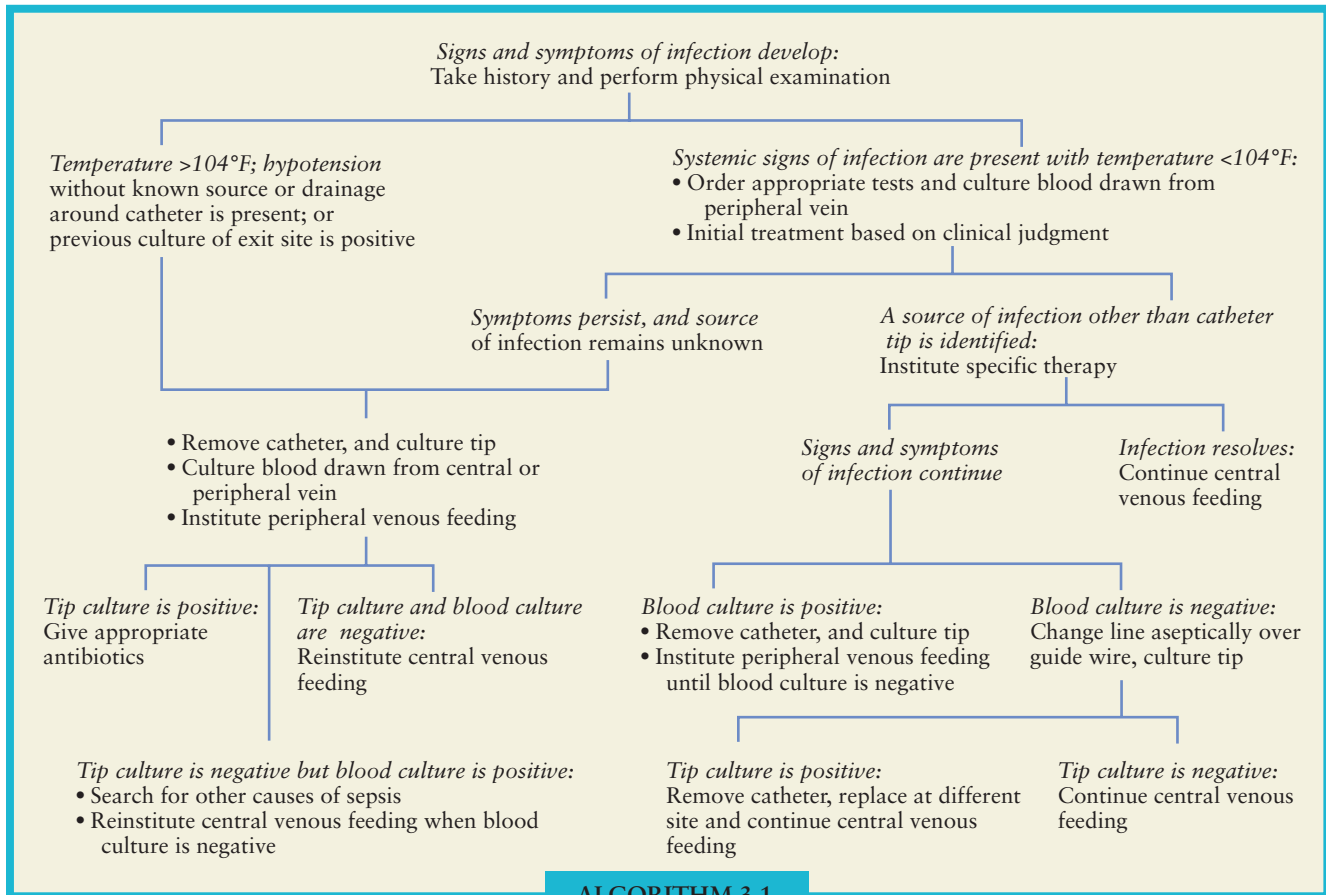

appropriate nutrition and maintenance of mucosal structure and function. Presumably, such efforts assist the gut in its role as a metabolic processing station and as a barrier.^{56–58}

Nutrition Support: Enteral Feedings

Enteral feedings are probably the best single method of maintaining mucosal structure and function if the bowel is functional. The trophic effects of luminal nutrition are key and the beneficial effects are well documented even if relatively small amounts of nutrients are provided.⁵⁹

Gut-specific Nutrients. It is now clear that the composition of the diet, as well as the route of delivery, plays an

important role in maintaining gut structure and function. Several gut-specific nutrients have been studied, but glutamine has received the most attention. Glutamine has been classified as a nonessential or nutritionally dispensable amino acid. Since this categorization implies that glutamine can be synthesized in adequate quantities from other amino acids and precursors, it has not been considered necessary to include glutamine in nutritional formulas. It has been eliminated from TPN solutions because of its relative instability and short shelf life compared to other amino acids. With few exceptions, glutamine is present in oral and enteral diets only at the relatively low levels characteristic of its concentration in most animal and plant proteins (about 7% of total amino acids).

ALGORITHM 3.1. Management of the total parenteral nutrition (TPN) patient who becomes septic.

Several recent studies have demonstrated that glutamine may be a conditionally essential amino acid during critical illness, particularly as it relates to supporting the metabolic requirements of the intestinal mucosa.^{56–58} In general, these studies demonstrate that dietary glutamine is not required during states of health, but appears to be beneficial when glutamine depletion is severe and/or when the intestinal mucosa is damaged by insults such as chemotherapy and radiation therapy. Addition of glutamine to enteral diets reduces the incidence of gut translocation, but these improvements are dependent on the amount of supplemental glutamine and the type of insult studied. Glutamine-enriched TPN partially attenuates the villous atrophy that develops during parenteral nutrition. The use of intravenous glutamine in humans appears to be safe and effective and it has been shown to diminish complications and reduce hospital stay.

In contrast to glutamine, short-chain fatty acids (SCFAs) are the primary energy source for colonocytes. Diets enriched in SCFAs have been shown to increase colonic DNA content and mucosal morphometrics as well as strengthen colonic anastomoses in rats. From diet, SCFAs are obtained from consumption of dietary fiber and fermentation in the colon by bacteria.

Other Factors to Support the Gut Mucosa. Specific growth factors that may promote intestinal mucosal growth have been implicated in a number of physiologic processes including growth, tissue repair, and regeneration. Among these is epidermal growth factor (EGF), a polypeptide secreted by submaxillary glands and by Brunner glands of the small intestine. The most widespread effect of EGF on the gastrointestinal

mucosa is the overall stimulation of DNA synthesis as evidenced by thymidine incorporation.

TECHNIQUES OF ENTERAL NUTRITIONAL SUPPORT

Enteral feeding causes the gut to release trophic factors, which improves intestinal mucosal integrity and reduces bacterial transmigration even if caloric goals are not met. It has also been associated with a decrease in postoperative infection rates and a significant increase in collagen deposition at anastomotic sites, increasing wound strength.^{60,61} Therefore, it should always be considered first over parenteral feeding in the surgically ill patient.

Transnasal (Nasogastric and Nasoduodenal) Feeding Catheters

The use of transnasal feeding catheters for intragastric feeding or for duodenal intubation is a popular adjunct for providing nutritional support by the enteral route. The stomach is easily accessed by the passage of a soft flexible feeding tube. Intragastric feedings provide several advantages for the patient. The stomach has the capacity and reservoir for bolus feedings. Feeding into the stomach results in the stimulation of the biliary and pancreatic axis, which is probably trophic for the small bowel, and gastric secretions have a dilutional effect on the osmolality of the feedings, reducing the risk of diarrhea.

Diarrhea is reported as a significant complication of enteral feeding, but can be influenced by formula administration, mode of administration, antibiotics, and alteration of bowel organisms.⁶² Additional complications include tube dislodgement, nasal ulcers, and electrolyte alterations. However, the major risk of intragastric feeding is the regurgitation of gastric contents resulting in aspiration into the tracheobronchial tree, which carries a mortality rate as high as 62%.⁶² This risk is highest for patients who have an altered mental sensorium or who are paralyzed.

The placement of the feeding tube through the pylorus into the fourth portion of the duodenum reduces the risk of regurgitation and aspiration of feeding formulas. To place a transnasal intraduodenal feeding catheter, the patient should be in the sitting position with the neck slightly flexed. This allows for the passage of a lubricated 8 French polyurethane feeding catheter, with a stylette in place, through the patient's nose in a posterior and inferior direction, bringing the catheter to the level of the pharynx. The head is brought back to a neutral position and the patient is instructed to swallow while the feeding catheter is passed into the esophageal lumen. The advancement of the catheter is continued for a distance of 45 to 50 cm. The stylette is then removed. Intravenous injection of a pro-motility agent, such as metoclopramide, can also be used if difficulty is encountered passing the tube postpyloric. Additionally, tubes can be positioned fluoroscopically if necessary. The patient who frequently removes the feeding catheter may be a candidate for a feeding tube bridle, as shown in Figure 3.10.

Placement of nasogastric or nasoduodenal tubes should always be confirmed radiographically prior to initiation of feedings. There are electromagnetic devices on the market that can track the path of the feeding tube during the placement procedure and may reduce the need for confirmatory

FIGURE 3.10. Use of a feeding tube bridle for patients who are prone to extubate the feeding catheter.

radiographs. However, these devices are not commonly used in the United States.⁶³

A variety of enteral formulas are commercially available and can be adjusted for calorie, nitrogen, or fiber content.

Technique for Gastrostomy Placement

A feeding gastrostomy should be considered for patients requiring long-term enteral nutrition and in patients with obstruction of the esophagus or locally advanced head and neck cancers that preclude eating. A temporary Stamm gastrostomy is a popular method for access to the gastric lumen and can be performed at the time of any major abdominal procedure. A square pursestring suture using 0 polypropylene with a 1-cm diameter is placed in the body of the anterior wall of the stomach. The ideal location is in the midportion of the stomach closer to the greater curvature in a relatively avascular area. A second hexagonal or octagonal pursestring suture, also 0 polypropylene, is placed outside the first one. The feeding catheter (often a Foley catheter) is then brought through a stab wound in the left upper quadrant of the abdominal wall. Using electrocautery, a puncture is made in the anterior portion of the stomach directly in the center of the concentric pursestring sutures. The feeding catheter is introduced into the gastric lumen and the inner concentric suture is secured in place. The second pursestring is then secured, inverting the gastric mucosa completely. The Foley catheter balloon is inflated and the stomach is drawn upward toward the anterior abdominal wall. Placement of Lembert silk sutures in all four quadrants around the Foley catheter secures the stomach to the anterior abdominal wall. The Foley is then secured to the skin by the placement of a bolstering disk at the base of the catheter exit site.

Technique of Percutaneous Endoscopic Gastrostomy

Percutaneous endoscopic gastrostomy (PEG) to provide access for gastric feedings can be performed without the need for a laparotomy or general anesthesia, and can be a useful modality for prolonged gastrointestinal decompression in patients with functional or mechanical obstruction.⁶⁴

Using intravenous sedation and topical anesthetic, a gastroscope is passed through the mouth into the esophagus and stomach. The light from the gastroscope is then transilluminated through the anterior abdominal wall in the epigastrium or left subcostal area. The abdomen is prepped and draped and a wheal of local anesthetic is injected right at the area of transillumination. A 1-cm vertical incision is made and an Angiocath or needle is inserted through the abdominal wall into the stomach under the direct vision of the gastroscope. A wire loop is passed through the catheter into the stomach and grasped with a snare passed through the gastroscope. The scope and wire loop are withdrawn through the mouth and the wire is looped through a corresponding wire on the end of the PEG tube. By pulling the wire out through the abdominal wall, the PEG tube is pulled in through the mouth and out the anterior abdomen while followed through the esophagus by the scope. The scope then visualizes the inner part of the PEG tube to be sure it seats properly against the stomach wall. The tube protruding through the abdominal wall is then bolstered at the exit site to prevent accidental dislodgment. The PEG tube can later be removed with just a hard pull.

Disadvantages of PEG tube placement include PEG site metastasis in patients with head and neck cancers, although this is rare, with fewer than 30 cases reported in the literature.⁶⁴ A mini-laparoscopic technique has been developed for

this reason and can also be used in patients where transillumination of the stomach is difficult or in patients who have had a subtotal gastrectomy with a small residual stomach.⁶⁵

Feeding Catheter Jejunostomy Placement and Witzel Jejunostomy

A feeding catheter jejunostomy should be considered following any major upper abdominal procedure if prolonged enteral nutrition support is anticipated, in patients with gastroparesis, gastric outlet obstruction, or functional or structural defects, but with normal small bowel.⁶⁶

The simplest method is a needle jejunostomy performed fairly quickly at the end of the definitive operation. A 14- or 16-gauge needle is used to create a tunnel subserosally approximately 30 to 40 cm distal to the ligament of Treitz and then the needle tip is introduced into the jejunal lumen. The feeding catheter is inserted through the needle and advanced 30 to 40 cm distally into the bowel lumen to the desired location, and the needle is withdrawn. The loop of jejunum is anchored to the parietal peritoneum with permanent sutures. The catheter is then secured to the skin with nylon sutures. A recent prospective study in major upper gastrointestinal surgery showed that feeding started earlier and progressed more easily with routine placement of a needle catheter jejunostomy.⁵⁹

A feeding jejunostomy can also be performed by utilizing the Witzel technique. A loop of proximal jejunum 20 to 30 cm from the ligament of Treitz is delivered into the wound. A pursestring suture is placed on the antimesenteric border of the bowel and an incision is made with electrocautery in the intestinal wall in the center of the pursestring suture. A 14 French red rubber catheter is inserted into the lumen of the jejunum and advanced distally. The pursestring suture is then secured in place. A serosal tunnel is constructed with 000 silk sutures from the catheter's exit site extending 5 to 6 cm proximally. The catheter is then delivered through the abdominal wall through a separate stab incision. This loop of intestine is anchored to the peritoneum with two 000 silk sutures spread over 2 to 3 cm to prevent twisting of the loop and possible obstruction. The catheter is secured to the skin with a 3-0 nylon suture. Jejunal feeding catheters can be used immediately for feeding purposes following the operation.

Complications of feeding jejunostomies include small bowel perforations or volvulus, intraperitoneal leaks, cellulitis, occlusion, and dislodgement. Needle and Witzel jejunostomies are associated with a 2% and 10% complication rate, respectively.⁶⁷

Jejunal tubes can also be placed endoscopically, usually via an extension tube through a gastrostomy. However, the extension tube can migrate proximally into the stomach and is prone to dysfunction. Direct insertion into the jejunum via endoscopy can provide a more stable access for feeding. The major advantage of this technique is tube patency, given that a 20 French tube can be inserted as opposed to the standard 9 French tube used with jejunal tube extensions.⁶⁶

TECHNIQUES OF PARENTERAL NUTRITIONAL SUPPORT

Parenteral nutrition has several advantages over enteral nutrition. Delivery access is much simpler and reliable, nutrition does not have to be discontinued for further surgical procedures, and patients meet caloric goals consistently. However, intravenous feeding is not without serious complications and is associated with increased morbidity, including bacteremia, and prolonged ventilator dependency.⁶⁰ Even so, it still remains a valuable adjunct in caring for the critically ill patient.

Peripheral Intravenous Feedings

Peripheral intravenous nutrition delivered via a fine-bore midline catheter offers an alternative means of nutrition in patients who do not require central venous access, have adequate peripheral veins, and require only short-term nutritional support.^{68,69} Indications for peripheral vein feeding include (a) as a supplement when enteral feedings can only be partially tolerated because of gastrointestinal dysfunction, (b) as a method of nutritional support when the gastrointestinal tract must be kept relatively empty for short periods during diagnostic workup, and (c) as preliminary feedings prior to subclavian catheter insertion in patients requiring TPN.

Peripheral intravenous feedings may be used for infusion of glucose, amino acid solutions, and fat emulsions. These solutions must be nearly isotonic to avoid peripheral vein sclerosis. Ten percent glucose solutions may be used to increase the efficacy of amino acid utilization. Fat emulsions can be administered simultaneously with glucose and amino acid solutions, because they provide an efficient fuel source and are isotonic. However, a disadvantage of peripherally administered solutions is limited caloric delivery to meet catabolic demands within tolerated fluid volumes.

The major complication of peripheral nutrition is peripheral vein thrombophlebitis (PVT), which necessitates routine daily catheter changes.⁷⁰ Several studies have shown that polyurethane cannulas develop fewer complications of thrombophlebitis and occlusion and can prolong feedings, compared to silicone cannulas.⁶⁸⁻⁷⁰ Feed additives such as heparin and hydrocortisone can also extend the total period of feeding attainable and reduce the incidence of PVT.⁹ In addition, long-chain triglycerides have been documented to prolong peripheral vein feeding by lessening the reaction of the venous endothelium to the nutritional infusate.⁷¹

Extravasation of infusion, occlusion of the catheter, and PVT are also influenced by the vein that is cannulated.⁷⁰ The cephalic vein is usually the vein of choice for standard intravenous insertion. However, the basilic vein is less narrow,⁷² thus causing decreased inflammation between the catheter and the venous endothelium, making PVT less likely.⁷⁰

A significant advantage of peripheral intravenous nutrition is avoiding central venous cannulation, which has considerable complications.

Central Venous Catheter Placement

The preferred method of access to the superior vena cava is by percutaneous cannulation of the subclavian vein. Alternate sites include the jugular approach, but with the catheter exiting in the neck region, this makes it more difficult to secure the dressing site and maintain sterility.

An individual who is experienced in the technique should perform the placement of a central venous catheter (CVC). The procedure is performed utilizing aseptic technique; the surgeon should wear a hat, mask, gown, and gloves. The procedure can take place in the operating room or in the patient's room if there is adequate lighting and assistance. An environment should be created to minimize patient anxiety, and informed consent must be obtained.

The following describes the standard Seldinger technique for insertion of a CVC via the subclavian vein; however, generally, the same approach is used when cannulating any central vein. The patient is placed in the Trendelenburg position with both arms at the sides and the head turned away from the site of insertion. The chest is shaved, prepped, and draped in a sterile fashion. Local anesthesia is infiltrated near the insertion site and the underlying tissues along the inferior border of the clavicle. The tip of the needle with the bevel pointed up is inserted into the skin and subcutaneous tissues at the midpoint

of the clavicle aiming for the suprasternal notch. The needle is directed parallel to the patient's bed, insinuating beneath the clavicle and at all times with negative pressure applied to the syringe. The prompt inflow of blood into the syringe indicates entrance into the subclavian vein and the needle is advanced a few millimeters to ensure the entire bevel is within the lumen of the vessel. The needle is then rotated 90 degrees with the bevel pointed toward the foot of the bed to help direct advancement of the guide wire into the superior vena cava. The patient is instructed to perform a Valsalva maneuver to prevent an air embolism, the syringe is disconnected from the needle, and the guide wire is passed through the needle lumen. The needle is then withdrawn over the guide wire. The passage of the wire through the needle should be met with minimal resistance and the needle should be removed only after 15 cm of the wire has been passed into the vessel. A small incision is made at the guide wire exit site and a dilator is passed over the wire. The dilator is then removed over the wire and is replaced by the catheter, which is fully advanced. The wire is withdrawn and the catheter is flushed with sterile saline. The catheter is then sutured into position, the insertion site cleaned, and a sterile dressing placed. A portable chest radiograph (CXR) is done to confirm placement of the catheter tip, which should be located either in the proximal to middle superior vena cava or at the atriocaval junction, and to rule out pneumothorax.

Complications of central venous cannulation include pneumothorax, arterial puncture, neck or mediastinal hematoma (when using the jugular approach), and hemothorax.⁷³ To reduce the risk of bleeding complications in patients with a platelet count below 50,000, consideration should be given to transfuse fresh platelets prior to catheter insertion. There have been several studies, including the National Institute for Clinical Excellence guidelines formulated in September 2002, and revised in August 2005, that advocate the use of ultrasound (US) as the preferred method of CVC insertion, particularly through the jugular approach, and as a means to decrease the aforementioned complications from 10.5% to 4.6%.^{73,74} US guidance in central venous cannulation also reduces time to insertion and may even decrease catheter-related sepsis.⁷⁵ If catheter sepsis is suspected, the CVC should be removed immediately and the tip cultured.

If a CVC is placed intraoperatively, the placement of the catheter is often not confirmed by CXR until several hours postoperatively. Incorrect CVC position, particularly in the right atrium, can be associated with adverse effects such as cardiac tamponade. Currently, studies are being conducted in the United States regarding electrocardiogram (ECG)-guided positioning for CVC placement. Using an ECG adapter connected to the central vein guide wire, an ECG monitor, and a right arm electrode, the CVC position in the right atrium would be confirmed by visualizing an elevated P wave on the monitor. The CVC could then be withdrawn until the P wave returned to normal configuration, indicating that the catheter was proximal to the atriocaval junction.⁷⁶ ECG-guided CVC positioning may decrease the frequency of CVC repositioning and repeated CXRs, and more importantly reduce cardiac complications.

An additional complication that is often overlooked is venous thrombosis. The clinical suspicion of subclavian vein thrombosis is only about 3%, whereas studies that use phlebography or radionuclide venography indicate that the incidence is as high as 35%.

Nutrition support of the surgical patient should strive to preserve body composition, provide needed nutrients, and minimize the inflammatory response to promote a decreased risk and better surgical outcome.

ACKNOWLEDGMENTS

We would like to thank Drs. Brian Cicuto and Melissa Boltz for their contributions to the Techniques section.

CHAPTER 4 ■ WOUND HEALING

ROBERT D. GALIANO AND THOMAS A. MUSTOE

KEY POINTS

- 1 The inflammatory phase of acute wound healing begins immediately after injury. The initial response to the disruption of blood vessels is bleeding.
- 2 The proliferative phase of acute wound healing begins with the formation of a provisional matrix of fibrin and fibronectin as part of initial clot formation.
- 3 The transition from the proliferative phase to the remodeling phase of acute wound healing is defined by reaching collagen equilibrium.
- 4 Reconstruction of the epithelial barrier (epithelialization) begins within hours of the initial injury.
- 5 Visible scarring occurs only when the injury extends deeper than the superficial dermis.
- 6 A practical definition of a chronic wound is one that has failed to heal within 3 months. Although there are a variety of underlying causes, most chronic wounds can be categorized as pressure sores, diabetic foot ulcers, or leg ulcers.
- 7 Most chronic wounds occur in older patients, are associated with underlying ischemia or tissue hypoxia, and are contaminated by bacteria in the setting of a biofilm.
- 8 It takes at least 3 weeks for collagen to undergo sufficient remodeling and cross-linking to attain moderate strength.
- 9 The primary difference between a keloid and a hypertrophic scar is that a keloid extends beyond the boundary of the original tissue injury.
- 10 Stem cells hold great promise for achieving true tissue regeneration, as opposed to scar formation, following an injury.

Wound healing is a fundamental homeostatic event in response to injury. The process of wound healing brings into play an exquisitely controlled cascade of molecular and cellular responses that are evolutionarily conserved across multicellular organisms, as well as regulation of these processes once repair is complete. Our understanding of the intricate crosstalk present between cells in the wound and other cells throughout the body has led to an appreciation that the process of tissue repair involves a coordinated interplay between metabolic, nervous, inflammatory, immune, and vascular systems, all played out within the microcosm of the wound. Similarly, the realization that blood-borne progenitor cells participate to varying degrees in the healing wound has elevated our once-parochial view that wound healing is strictly a local phenomenon to the conceptualization of wound healing as a systemic process. Increased understanding of the cellular and molecular events involving growth factors and cytokines and the realistic prospects for pharmacologic manipulation have focused a great deal of research interest from a broad range of disciplines. The field of wound healing has expanded in complexity as well as scope: basic scientists as well as clinicians and allied health professionals all have contributed to advances in this fascinating field. Despite our greater understanding of the complexities involved, however, there remain a set of core principles that serve to direct and guide patient care. This chapter outlines a basic set of concepts regarding wound healing, with emphasis on the clinical principles of basic surgical techniques; the care of surgical incisions; and the management of both acute and chronic open wounds.

NORMAL WOUND HEALING

Wound healing is the body's response to injury. Injury can be acute or chronic and involve multiple tissues, but wound healing is most clearly illustrated by examining the response to full-thickness injury (e.g., a cut or an incision) to the epidermis and dermis. This injury sets in motion a sequence of interrelated reparative forces. Although the events overlap in time, it

is helpful to consider the process as stages or phases of wound healing; these are presented as separate events. This provides for clear conceptualization of the individual events and conforms to standard conventions. These events, however, do not occur independently, and the degree of temporal overlap is significant (Fig. 4.1).¹

Every tissue in the body undergoes reparative processes after injury. Bone has the unique ability to heal without scar. Liver has the potential to regenerate parenchyma and is the only organ that has maintained that ability in the adult human. With these exceptions, all other human tissues heal with scar. This chapter reviews the healing process of human skin with particular emphasis on surgical applications. Delineation of the individual mediators that participate in this process is still evolving, so the emphasis is on the underlying physiologic processes and the patterns of response.

Inflammatory Phase

- 1 The inflammatory phase of acute wound healing begins immediately after injury. The initial response to the disruption of blood vessels is bleeding. The homeostatic response to this is clot formation to stop hemorrhage. Platelet plug formation initiates the hemostatic process along with recruitment of clotting factors activated by collagen and basement membrane proteins exposed by the injury. Fibrin, converted from fibrinogen by the clotting cascade, binds the platelet plug and forms the provisional matrix for the cellular responses that follow. After injury, transient vasoconstriction is mediated by catecholamines, thromboxane, and prostaglandin F_{2a} (PGF_{2a}). Platelet degranulation, the emptying of the granules into the extracellular space, provides the contents of α granules and dense granules, most notably platelet-derived growth factor (PDGF) and transforming growth factor- β ($TGF-\beta$). These substances initiate chemotaxis and proliferation of inflammatory cells, beginning the inflammatory response that will ultimately heal the wound (Table 4.1). Transient vasoconstriction is necessary to decrease blood loss at the time of the initial

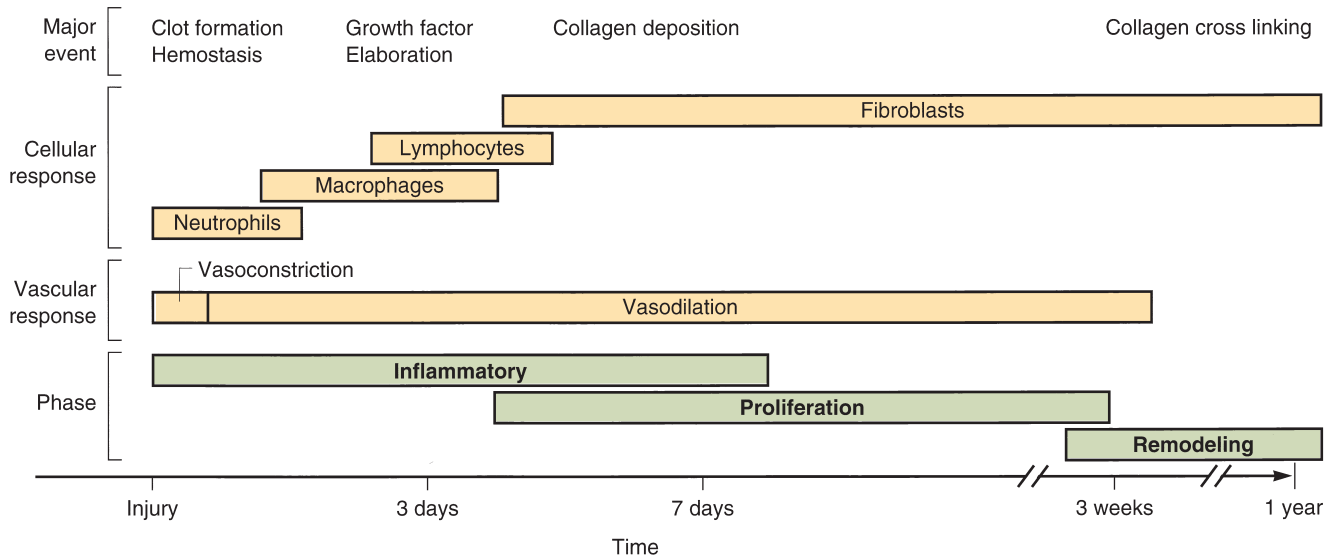

FIGURE 4.1. Timeline of phases of wound healing with dominant cell types and major physiologic events.

wounding and also to allow clot formation. Vasoconstriction lasts for 5 to 10 minutes. Once a clot has been formed and active bleeding has stopped, vasodilatation increases local blood flow to the wounded area, supplying cells and substrate necessary for further wound repair. The vascular endothelial cells also deform, increasing vascular permeability. The vasodilatation and increased endothelial permeability are mediated by histamine, PGE_2 , and PGI_2 (prostacyclin), as well as vascular endothelial cell growth factor (VEGF). These vasodilatory substances are released by injured endothelial cells and mast cells and enhance the egress of cells and substrate into the wounded tissue (Fig. 4.2).

At this stage, the wound is full of debris from the initial injury. This material consists of a mixture of injured, devitalized tissue (fat, muscle, epithelium), clot (platelets, erythrocytes, fibrin), bacteria (from the skin surface and external environment), extravasated serum proteins (glycoproteins and mucopolysaccharides), and foreign material introduced at the time of injury (suture, dirt). During the next several days, the

wound is cleared of bacteria, devitalized tissue, and foreign material by recruited and activated phagocytic cells. Polymorphonuclear leukocytes (PMNs) begin to arrive immediately, attaining large numbers within 24 hours. The process of clearing the wound of debris usually takes several days, but the time varies depending on the amount of material to be cleared. The PMNs are followed temporally by macrophages, which appear in wounds in significant numbers within 2 or 3 days. The macrophages are mononuclear phagocytic cells derived from circulating monocytes or resident tissue macrophages. They complete the process of removing all material not necessary for the ensuing steps of wound healing.

In the absence of significant bacterial contamination, macrophages promptly replace PMNs as the dominant cell type during the inflammatory phase. The role of the macrophages is not limited to phagocytosis.² In addition, macrophages are the sources of more than 30 different growth factors and cytokines. These growth factors induce fibroblast proliferation, endothelial cell proliferation (angiogenesis), and extracellular matrix production, and they recruit and activate additional macrophages. The result is the induction of a wound healing amplification cycle as growth factors recruit macrophages and elicit additional growth factor release. Specific antibodies that destroy PMNs or block certain aspects of amplification function (such as adhesion) have shown that experimental wounds heal normally in the absence of PMNs, but that healing is significantly impaired without functional macrophages (even in the absence of bacteria). These studies confirm the dominant role of the macrophage in the inflammatory phase of wound healing. The amplification process is so powerful that only scattered fibroblasts and endothelial cells are seen in a surgical incision or at the edge of an open wound at day 3, but by day 5 the wound is very cellular with active proliferation. By day 7, the incisional wound is strong enough to allow suture removal, and proliferating fibroblasts and angiogenesis give the wound an appearance similar in many respects to the stroma surrounding tumors.

Lymphocytes also appear in wounds in small numbers during the inflammatory phase. The role of lymphocytes in the wound healing process remains to be clarified but is thought to be related more to chronic inflammatory processes than to the initial response to wounding. Recently, it has become more appreciated that within this heterogeneous population of cells are several distinct subpopulations of blood-borne progenitor cells that likely contribute in varying degrees to tissue repair.

TABLE 4.1

(*continued*)

These will be discussed further later. Because recombinant growth factors are available in sufficient quantities for clinical use, the prospect of using growth factors as pharmacologic agents to stimulate wound healing (and potentially modulate abnormal scarring) has been the focus of much research. Dozens of growth factor studies have been performed in humans, based on animal studies that have demonstrated wound healing activity by about a dozen different growth factors (PDGF, TGF- β 1, TGF- β 2, TGF- β 3, fibroblast growth factor 2 [FGF2], FGF7, keratinocyte growth factor [KGF], granulocyte-macrophage colony-stimulating factor [GM-CSF], insulinlike growth factor 1 [IGF-1], IGF-1-binding protein [IGFBP1], and epidermal growth factor [EGF] represent a partial list). To date, only PDGF has been approved.³ After a 7-year process involving 1,000 patients, PDGF (Regranex) was approved in 1997 by the U.S. Food and Drug Administration

(FDA) for use in diabetic foot ulcers. The failure of so many clinical trials to demonstrate efficacy is a reflection of both the complexity and variability of human wounds, which make it difficult to demonstrate efficacy in all but the largest of studies and to demonstrate the multiple etiologic factors that result in chronic wounds.

Another product, an artificial skin equivalent made of a dermislike matrix covered with cultured epithelium from heterologous human foreskins (Apligraf), was approved by the FDA in 1998 for use in venous ulcers of more than 1 year's duration that had failed other therapies. This product's main effect is most likely due to the delivery of growth factors produced by the neonatal cells. Increased knowledge of the role of growth factors in wound healing has also provoked the evaluation of strategies using other pharmacologic agents to indirectly modulate growth factor levels in wounds.

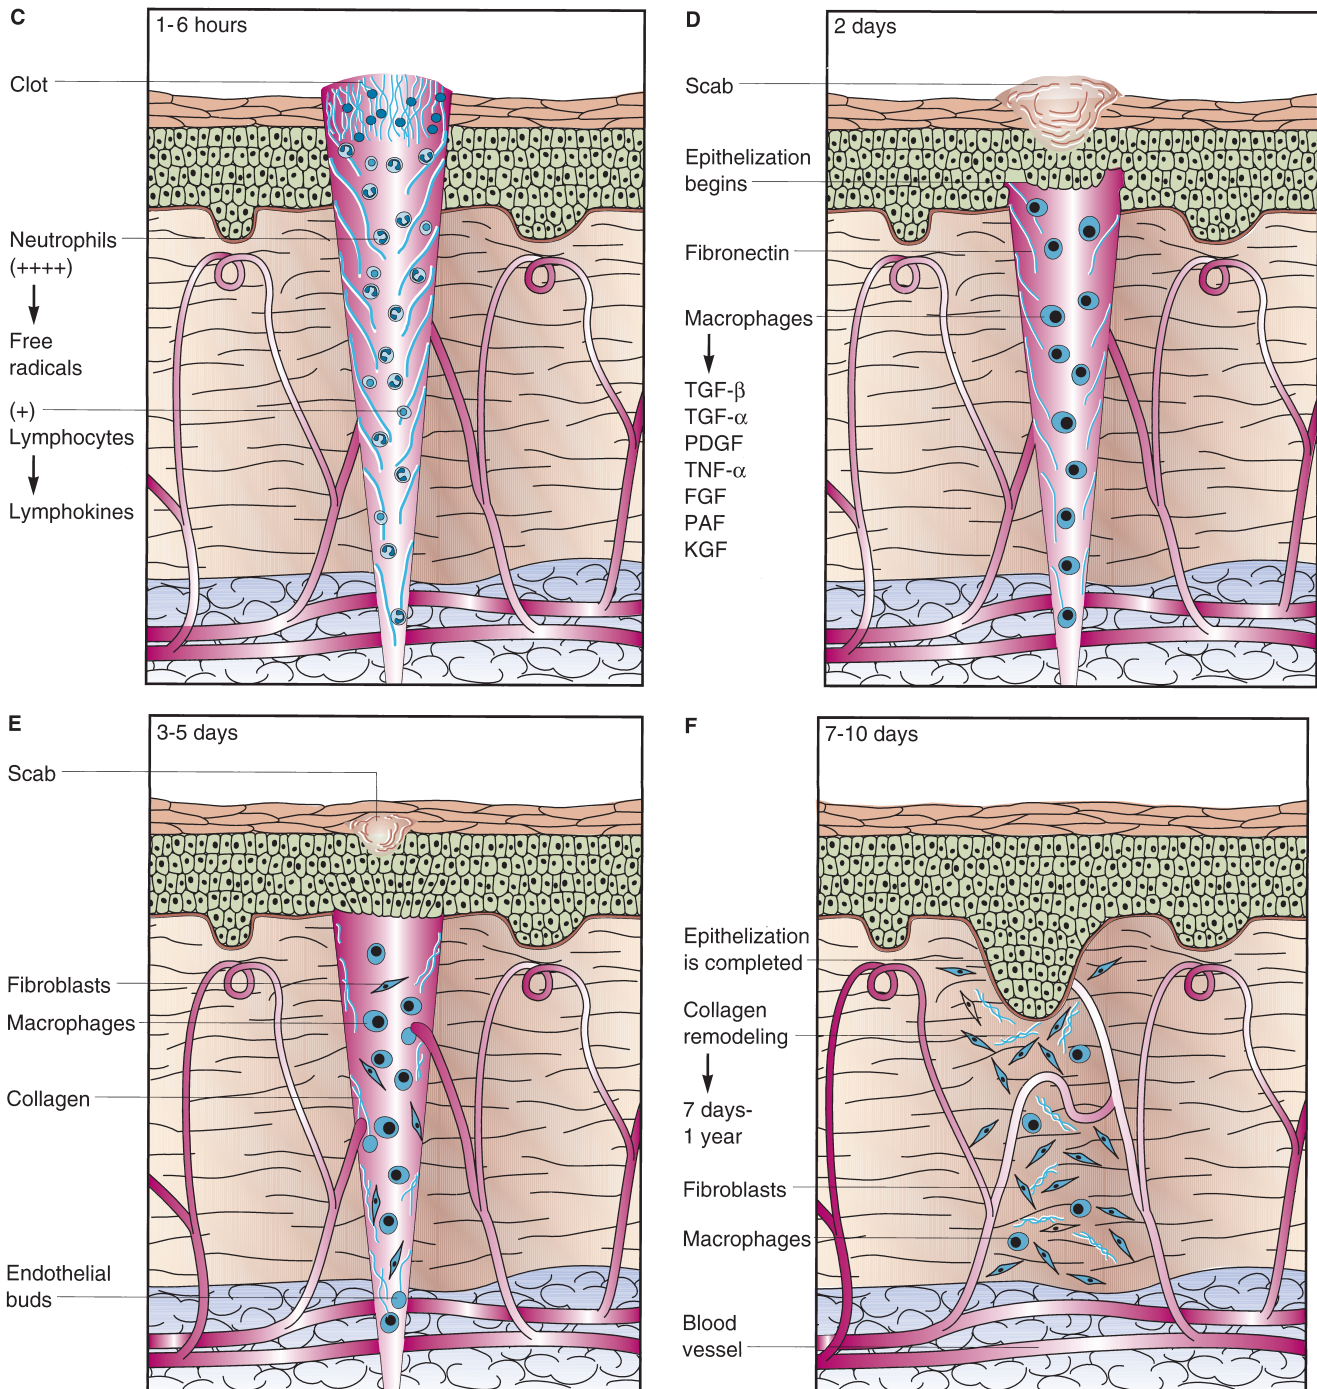

FIGURE 4.2. (Continued)

Proliferative Phase

- 2 The proliferative phase begins with the formation of a provisional matrix of fibrin and fibronectin as part of initial clot formation. Initially, the provisional matrix is populated by macrophages; however, by day 3, fibroblasts appear in the fibronectin–fibrin framework and initiate collagen synthesis. Fibroblasts proliferate in response to growth factors to become the dominant cell type during this phase. Growth factors produced by macrophages simultaneously induce angiogenesis, which induces the ingrowth and proliferation of endothelial cells, forming new capillaries. The process of neovascularization is driven in large part by the local tissue

hypoxia present in the wound center, which in turn is orchestrated by the hypoxia-inducible factor-1 (HIF-1). This master transcription factor functions as the switch that turns on angiogenic processes, metabolic adaptations to hypoxia, an increase in iron transport, and erythropoiesis, functioning across local, regional, and systemic levels to restore blood flow to an injured area. Initially, the angiogenic cascade unleashed by HIF-1 results in a hypervascular network, which will be pruned later. This neovascularity is visible through the epithelium and gives the wound a pink or purple-red appearance. Capillary ingrowth provides the fibroblasts with oxygen and nutrients to sustain cell proliferation and support the production of the permanent wound matrix. This matrix is composed

FIGURE 4.3. A: Type I collagen showing triple helix and intramolecular cross-links. B: Intermolecular cross-links provide tensile strength. C: Assembly of collagen fibrils, fibers, and fiber bundles.

of collagen and proteoglycans or ground substance and replaces the provisional fibronectin–fibrin matrix.

Collagen is the dominant structural molecule in the wound matrix and in the final scar. This is not surprising because collagen is the principal structural protein in skin, bone, and, indeed, all human tissues. Collagen is synthesized into an organized cablelike network in a multistep process with both intracellular and extracellular components (Fig. 4.3). The collagen molecule has abundant quantities of two unique amino acids, hydroxyproline and hydroxylysine. The hydroxylation process that forms these amino acids requires ascorbic acid (vitamin C) and is necessary for the subsequent stabilization and cross-linkage of collagen. Procollagen is formed within the fibroblasts as a long linear amino acid segment with regular repeats of hydroxyproline every third amino acid and with terminal extension peptides. Procollagen molecules aggregate in the case of type I collagen (the most common) as three α chains to form a triple-helical complex (Fig. 4.3A). The triple helix is maintained by intramolecular disulfide bonds between specific

cystine residues. Procollagen is secreted in its triple-helical form; extracellular peptidases cleave the extension peptides at the amino and carboxy termini, leaving the central collagen molecule. Collagen cross-linking (Fig. 4.3B) then occurs in the extracellular space as the collagen molecules aggregate into larger structures. Lysyl oxidase catalyzes the conversion of lysine and hydroxylysine into aldehyde forms. These aldehydes form intermolecular bonds by undergoing spontaneous condensation. This produces stable, cross-linked collagen fibrils. These intramolecular and intermolecular bonds provide strength and stability. As the wound matures, fibrils cross-link to form large cables of collagen, providing increased tensile strength (Fig. 4.3C). The wound is then more appropriately considered a scar.

Although there are many types of collagen, type I predominates throughout the body. The principal collagen in scar is type I, with lesser amounts of type III collagen present. Other collagen types make important contributions to the basement membrane, cartilage, and other structures (Table 4.2).

TABLE 4.2**COLLAGEN TYPES**

TYPE	PROPERTY OF AGGREGATE UNIT	TISSUE DISTRIBUTION
I	Rigid fibrils	All connective tissue except cartilage
II	Rigid fibrils	Cartilage and vitreous
III	Elastic fibrils	Elastic tissue (e.g., fetal skin, blood vessels, uterus)
IV	Sheet	Basement membrane
V	Fibril	Widespread
VI	Beaded filaments	Widespread
VII	Anchoring fibrils	Interface of basement membrane and underlying stroma
VIII	Sheet	Descemet membrane
IX	Fibril	Hyaline cartilage
X	Sheet	Hypertrophic cartilage
XI	Fibril	Hyaline cartilage
XII	Fibril	Similar to type I

Remodeling Phase: The Formation of Scars

- 3 The transition from the proliferative phase to the remodeling phase is defined by the achievement of collagen equilibrium. Collagen accumulation within the wound reaches a maximum within 2 to 3 weeks after wounding. Although supranormal

rates of synthesis and degradation continue throughout remodeling, there is no further change in total collagen content.⁴ Tensile strength gradually increases as random collagen fibrils are replaced by organized fibrils with more intermolecular bonds. During the initial phase of wound healing, there is a relative abundance of type III collagen in the wound. With remodeling, the normal adult ratio of 4:1 (type I to type III) collagen is restored. Under normal wound healing conditions, the capillary density gradually diminishes, and the number of fibroblasts is reduced. The wound loses its pink or purple vascular color and becomes progressively pale. The collagen undergoes constant remodeling. New collagen is formed, and collagen degradation by specific collagenases is ongoing. Collagenase activity is balanced against new production of collagen to produce a steady state. As equilibrium is achieved, the collagen fibrils align themselves in a longitudinal arrangement as dictated by stress placed on the wound. Scars never achieve the degree of order achieved by collagen in normal skin or tendons, but they do increase in strength for 6 months or longer, eventually reaching 70% of the strength of unwounded skin (Fig. 4.4).

The other important component of the extracellular matrix is the ground substance or proteoglycans. These substances are composed of a protein backbone with long hydrophilic carbohydrate side chains. The hydrophilic nature of these molecules accounts for much of the water content of scars. In the early immature wound, there is a disproportionately large amount of proteoglycans (particularly hyaluronic acid). During the maturation phase, the proteoglycan content returns to a level that closely approximates that of normal skin.

Until recently, the extracellular matrix (predominantly collagen and proteoglycans) was thought to be inert. It is becoming increasingly clear, however, that extracellular matrix signals certain cells through cell attachment receptors (integrins) and serves as a reservoir for growth factors. Via integrin receptors, the extracellular matrix influences intracellular signal transduction with an impact on cell motility and migration,

FIGURE 4.4. Relation of the rate of collagen synthesis to the gain of tensile strength of rat skin wounds. (Adapted from Madden JW, Peacock EE Jr. Studies on the biology of collagen during wound healing. 1. Rate of collagen synthesis and deposition in cutaneous wounds of the rat. *Surgery* 1968;64:288.)

cellular proliferation, and growth factor production. The role of proteoglycans as signaling molecules is just beginning to be understood. In addition, mechanical forces on tissue are transmitted from the matrix to the cells that are attached to the matrix, and increasing evidence indicates that mechanical forces result in signal transduction, which can result in cellular proliferation, apoptosis, and other signal transduction processes.⁵

Epithelialization

4 The skin is composed of two layers, the epidermis and the dermis. The outermost layer, the epidermis, is the protective barrier that forms the external interface between the body and the environment. The epidermis protects against water loss, allowing the other cells of the body to live in a liquid environment, as well as forming a barrier to bacteria and other environmental factors. Reconstruction of the epithelial barrier (epithelialization) begins within hours of the initial injury. As an initial step, epithelial cells from the basal layer at the wound edge flatten and migrate across the wound, completing wound coverage within 18 to 24 hours in a coapted surgical wound. The cells along the margin are also dividing to re-form the characteristic basilar to apical differentiation of multilayered mature epithelium (see later). Epithelial cells exhibit contact inhibition; that is, they continue to migrate across an appropriate bed until a single continuous layer is formed. Epithelial cell migration occurs by a process in which the epithelial cells send out pseudopods, attaching to the underlying extracellular matrix by integrin receptors. Bacteria, large amounts of protein exudate from leaky capillaries, and necrotic tissue all compromise this process, delaying epithelialization. Delayed epithelialization results in a more profound and prolonged inflammatory process, thereby contributing to unsatisfactory or hypertrophic scarring. There is increasing evidence that reestablishment of a mature epithelium with a multilayered keratin layer (stratum corneum), which completely restores the normal water barrier, is an important component of the scar resolution process and downregulation of the inflammatory cascade. In addition, it is clear that establishment of an intact epithelial cover begins the process of wound resolution, a process that is still not well understood. Cell signals from the epithelium have been implicated in the pathogenesis of keloids, and reestablishment of an epithelial barrier by skin graft or flap results in reduction in inflammation and apoptosis of the underlying dermis.⁶

In superficial, partial-thickness wounds, epithelialization results from migration of epithelial cells from remaining dermal appendages, sweat glands, and hair follicles (Fig. 4.5). Epithelial stem cells from the hair follicle and interfollicular stem niche also repopulate a significant amount of the epidermis. This is relatively rapid because the distance between hair follicles and sweat glands is short; epithelialization is usually complete within 7 to 10 days. In deeper injuries, however, such as deep second-degree burns, the combination of increased necrosis and fewer remaining dermal appendages can result in delayed epithelialization with prolongation of the inflammatory process.

A partial-thickness burn or abrasion that requires more than 2 weeks to epithelialize has a high incidence of hypertrophic scarring. The increased scarring is presumably secondary to prolonged inflammation. This can be minimized by achieving a closed wound through skin grafting or other techniques. With a partial-thickness wound or abrasion, it is important to achieve rapid epithelialization through maintaining a moist environment and preventing bacterial proliferation by continually removing protein-containing exudates that provide a substrate for bacterial growth.

In full-thickness injury, the entire dermis is destroyed or removed. Epithelialization occurs only from the margins of the wound, at a maximal rate of 1 to 2 mm/d. In practice, adequate coverage of sizable wounds is rarely achieved. Thus, lower leg ulcers rarely heal faster than 1 cm/mo; that is, a 2-cm-diameter ulcer typically takes 2 months to heal under ideal conditions. In an open wound, the rate of epithelialization is critically dependent on the vascularity and health of the underlying granulation tissue (neodermis) across which it migrates. In addition, cellular migration is dependent on the condition of the matrix. Excess bacterial burden results in secondary PMN influx with protease degradation of the matrix and a hostile environment for cellular attachment and migration. Thus, although chronic wounds are manifested by a failure of epithelial migration, the cause is most often a problem in the underlying wound bed, such as local ischemia or excessive bacterial colonization.

The epithelial cells alone provide little strength when not anchored to dermis. They are therefore prone to injury. The basal epidermal cells are attached to the underlying dermis by hemidesmosomes. These structures attach to keratin filaments within the epithelial cells. The hemidesmosomes connect by a series of intermediate proteins to anchoring filaments, long proteins that intertwine with the collagen network of the dermis. Intact epithelium is resistant to sheer forces due to these strong dermal attachments. Without an adequate dermal base, however, epidermis provides unstable wound coverage and is characterized by chronic and recurrent wound breakdown; this is frequently noted in a heavily cicatrized bed.

After the first layer of cells restores the epithelial barrier, additional layers develop, restoring the basilar-to-apical order. As the cells mature, they resume keratin formation. This regenerates the stratum corneum of the epidermis, completes the restorative process of epithelialization, and provides stable coverage.

Scar

5 Visible scarring occurs only when the injury extends deeper than the superficial dermis. Superficial abrasions and burns usually heal without scarring even if the superficial dermis is involved, because a thin layer of scar in the superficial dermis is not visible. Whenever the dermis is incised, a scar forms. Scar formation at the molecular level is due to disorganized collagen. In response to injury, dermal integrity is restored by collagen synthesis and deposition. Over the time of scar maturation (6 months to several years), scar remodeling results in progressive collagen linking and increased organization, but the parallel organized collagen layers of normal skin are never completely reconstituted, resulting in visible scar. The prominence of the scar is variable and can be minimized by location and closure technique. If an incision is made, however, a scar is inevitable. The quality of the scar is impacted by a number of factors. The underlying genetic tendency to scar is a significant factor. It is well known that some African Americans form keloids from even minor insults, and approximately 5% to 10% of African Americans are keloid prone. Many Asians (as many as 50% of Chinese, Korean, and Japanese) have some tendency to form hypertrophic scars. Elderly patients heal with less inflammation and rarely form hypertrophic scars. Scars parallel to collagen fibers in relaxed skin tension lines form much better scars than those perpendicular to relaxed skin tension lines. As discussed previously, mechanical forces stimulate cell proliferation and collagen synthesis, so that scars closed under tension after skin excision or in locations subjected to tension such as the sternum or shoulder are prone to scar hypertrophy.⁷

FIGURE 4.5. Reepithelialization of a partial-thickness wound. (*continued*)

Stretch marks are a unique type of scar. Stretch marks occur when the collagen fibers in the dermis are stretched to the point of disruption, but the epidermis is not disrupted. This results in scar formation in the dermis that is visible through an intact, unscarred epidermis. There is no treatment for stretch marks other than excision of the skin (which of course results in scar from wound closure) or tissue destruction, which can in exceptional circumstances result in wound contraction and some shrinkage of the stretch marks (the rationale for treating stretch marks with laser).

Clinical Implications

Optimal Outcomes from Surgical Closure. This review of normal wound healing has numerous practical implications to the care of wounds and surgical incisions in order to ensure uncomplicated, expeditious healing as well as produce an optimal scar. Meticulous hemostasis reduces the inflammation and phagocytosis necessary to clear the wound of blood. The use of electrocautery should be judicious. Electrocautery results in a band of tissue necrosis that varies in thickness in relation to

FIGURE 4.5. (Continued)

C

D

heat generated. The benefits in hemostasis from cautery must be balanced with the thermal injury that results, to minimize stimuli for inflammation. Atraumatic handling of tissue decreases the load of necrotic or nonviable cells at the wound margin. This is best achieved using fine forceps or skin hooks to retract and assist in coapting the dermis. Crush injury to the epidermis with forceps should be avoided. Deep sutures are

best placed only into collagen-laden structures that can hold tension, that is, fascia and dermis. These tissues have the tensile strength to hold sutures under tension. Fat does not contain collagen and does not hold tension. Therefore, fatty tissue should not be sutured as a separate layer. Dead-space obliteration and fluid evacuation are best achieved by suction drainage rather than by adding additional foreign material to the

wound in the form of suture material. Therefore, in closing a laparotomy incision, even in a morbidly obese patient with a large panniculus, the closure should be limited to the abdominal fascia, the skin, and rarely the Scarpa fascia. The choice and proper use of suture material is also important. Sutures should be chosen to provide the appropriate amount of strength to prevent dehiscence; this is balanced by the inflammation that results as a suture dissolves. In the skin, an absorbable intradermal suture that dissolves over a prolonged period will result in prolonged inflammation and a prominent scar. Well-placed sutures will also minimize the incidence of suture knot extrusion, which can also compromise the final appearance of the scar.

Under normal circumstances, epithelialization of an incision is complete within 24 to 48 hours, and there is no reason to protect the incision from water beyond this time. Allowing the patient to wash or shower 1 or 2 days after surgery has significant psychological benefit and gently débrides the incision and keeps it clean by rinsing away surface bacteria and debris. Blood and protein exudate are an excellent culture media for any skin surface bacteria. Showers reduce the chance of bacterial accumulation in surface crusts along the incision and on the sutures. This decreases inflammation and prevents breakdown of the fragile epithelial layer over the incision, improving the quality of the scar. Once the incision has epithelialized and the epidermis has matured, there is increasing acceptance of the concept that covering immature epidermis for a period of as long as 2 months with paper tape, silicone gel sheeting, or other materials improves scar outcome, most likely due to restoration of the water barrier function of mature stratum corneum.⁷

OPEN WOUNDS (ACUTE)

Open wounds, whether ulcers or open surgical incisions closing by secondary intention, heal with the same sequence of inflammation, matrix deposition, epithelialization, and scar maturation as previously described. However, there are some important differences. In the closed (sutured) incisional wound, the healing process progresses through an orderly temporal sequence. In an open wound, the healing events are spatially separated. In the healing wound, a bed of granulation tissue forms over the exposed subcutaneous tissue. Granulation tissue is composed of new capillaries; proliferating fibroblasts; and an immature matrix of collagen, proteoglycans, substrate adhesion molecules (including fibronectin, laminin, and tenascin), and acute and chronic inflammatory cells. In addition, there are variable amounts of bacteria and protein exudate, depending on the condition of the wound. At the advancing edge of epithelium, the process of acute inflammation is present. Behind the advancing edge, there is a proliferative area, and further behind, the scar is maturing and remodeling. An understanding of the biologic principles of wound healing has direct clinical implications in wound care, particularly in the case of chronic wounds (e.g., pressure sores, lower leg ulcers, diabetic foot ulcers).

The most important clinical factor in the healing of surgical incisions is the gain in tensile strength of the wound. This depends almost entirely on collagen deposition. The rate of collagen synthesis determines the initial wound strength; ultimate wound strength is determined by the degree of collagen organization and cross-linking. The healing of open wounds is defined primarily by epithelialization, and successful healing is related more to the maintenance of epithelial integrity than to the tensile strength of the scar. As discussed earlier, the rate of epithelialization in open wounds is limited by the rate of migration of the proliferating epithelial edge. Factors that regulate epithelial migration are an area of active research. There is clear evidence that the extracellular matrix

(collagen, fibronectin, basement membrane proteins, and glycosaminoglycans) is composed of structural elements that are not inert. They function as an essential substrate, with adhesion molecules regulating intercellular communication. The cellular occupants of the matrix express specific receptors that recognize amino acid sequences on the matrix proteins. This allows for cellular attachment at specific sites, cell locomotion, and intracellular signal transduction. Rapid epithelialization is therefore dependent on an optimal matrix, synthesized by the underlying granulation tissue, as well as on optimal delivery of nutrients and oxygen by an adequate blood supply. The rate of epithelialization is also inversely related to the degree of bacterial presence in the wound, a variable that is directly related to the quality of the granulation tissue present.

Inflammatory cells in open wounds, especially the macrophages, release growth factors. Growth factors enhance migration and proliferation of fibroblasts and endothelial cells in wounds. In an open wound, this leads to the formation of granulation tissue, the cobblestonelike pink surface of healthy new tissue. The ability of an open wound to form granulation tissue is governed by the blood supply to the tissue and the relative absence of devitalized tissue and bacteria. Therefore, wounds that form granulation tissue should heal or be amenable to surgical closure with flaps or skin grafts. Wounds that do not form granulation tissue are very likely to be recalcitrant to all treatments except those directed at the underlying cause of the failure to form granulation tissue, that is, vascular bypass to restore adequate blood flow to an ischemic extremity wound or a vigorous surgical débridement to clear the wound of contaminating bacterial pathogens that impair the development of healthy granulation tissue and impede epidermal migration.

Débridement deserves mention, as it is frequently underutilized in clinical care. It is a simple technique that is unglamorous in comparison to other more complex surgical operations, yet is essentially critical to ensuring healing in a contaminated surgical wound. Débridement is a term that refers to clearance of tissue that is unnecessary and counterproductive to healing, and in practical terms usually refers to bacteria and necrotic, devitalized tissue. Débridement can take the form of nonsurgical techniques, such as autolytic, enzymatic, or biologic approaches, or alternatively a surgical technique can be used. The astute clinician will tailor the degree of débridement necessary to achieve the desired outcome while minimizing removal of healthy healing tissue. The importance of débridement is most clearly seen in chronic wounds, which will be more fully discussed later. The process of débridement removes bacteria and their products, which serve to propagate a counterproductive hyperinflammatory phase and which divert metabolic resources away from the healing wound. In a chronic wound, bacterial critical colonization often will result in a hyperinflammatory loop that is best short-circuited by a judicious débridement, allowing the wound to progress toward healing (Fig. 4.6).⁸

Wound Contraction

Wound contraction is an important event that contrasts the healing of open wounds with closed incisions. When open wounds contract, the surrounding skin is pulled over the wound to reduce its size. This can occur much faster than epithelialization. In addition to increasing the speed of wound closure, another advantage is that the open wound is resurfaced by the normal sensate skin surrounding the wound. Most animals are loose skinned, meaning that the skin (epithelium, dermis, subcutaneous fat) is only loosely attached to the underlying muscle fascia. Some animal wounds heal almost entirely by contraction; for example, a 2-cm ulcer heals to a

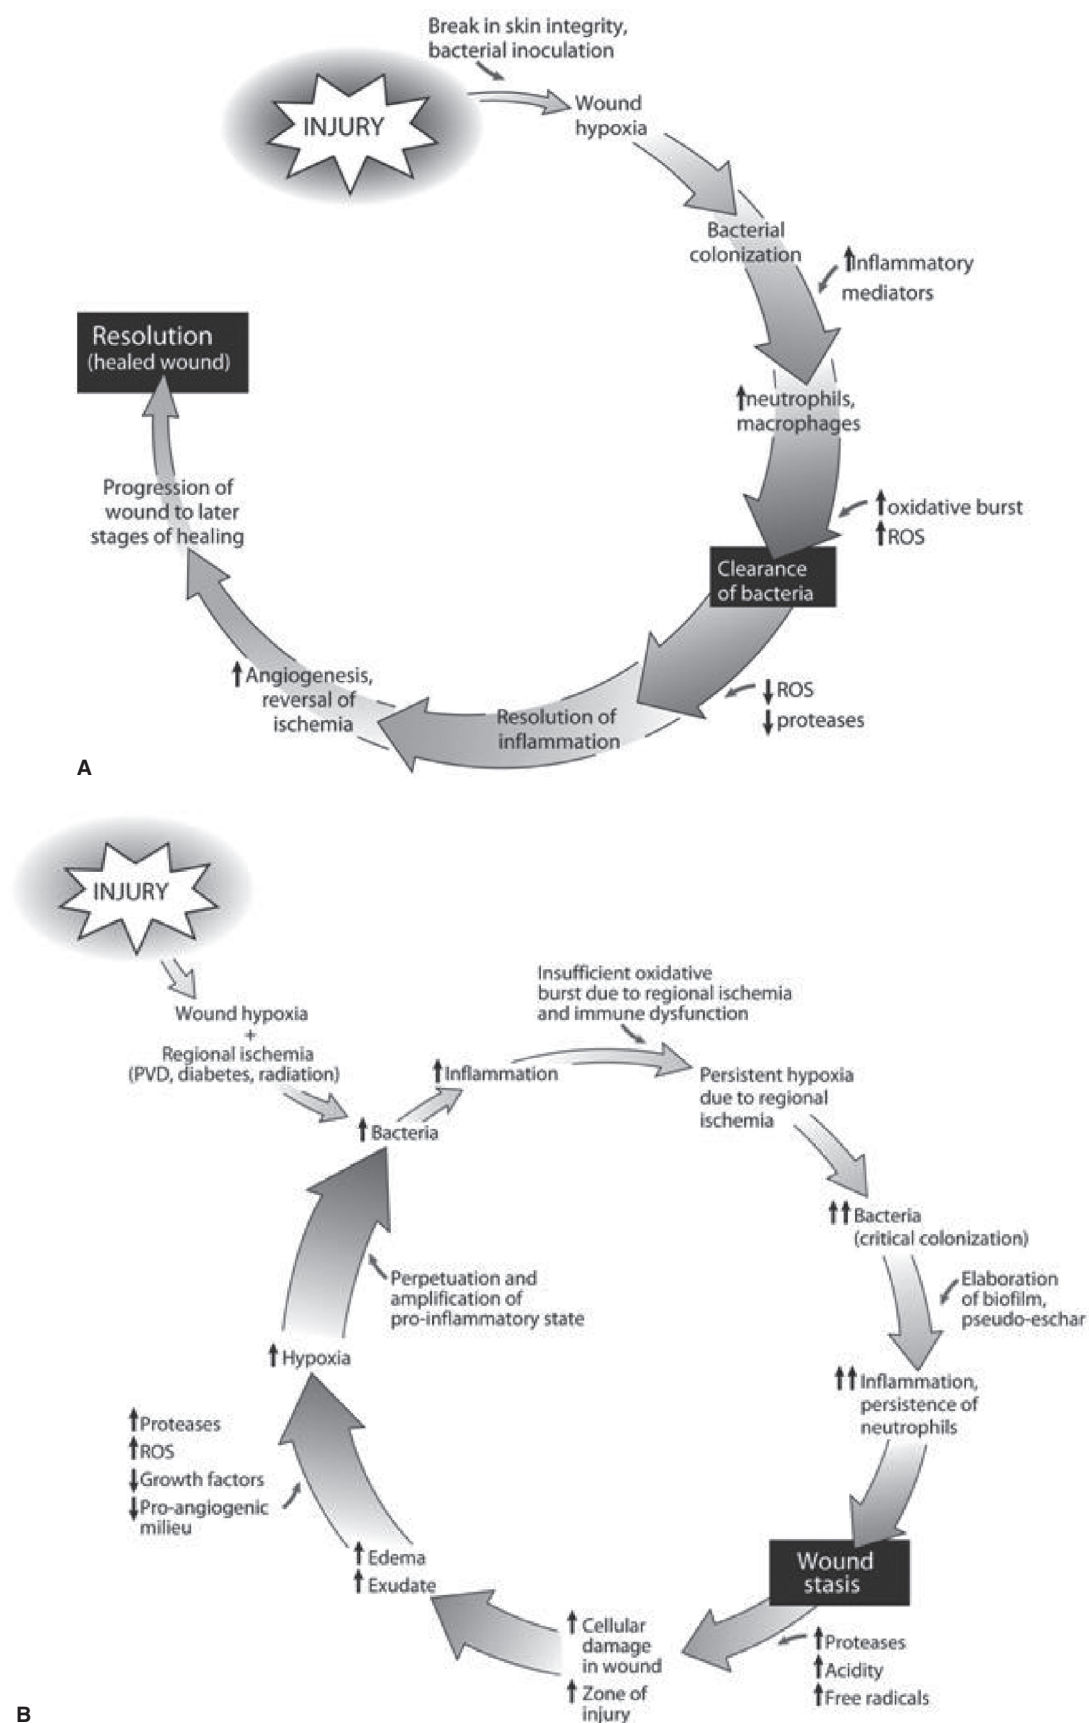

FIGURE 4.6. The inflammatory cascade in wound repair. **A:** In healthy patients with adequate tissue perfusion, the inflammatory burst is self-limited as reactive oxygen species (ROS) serve to clear bacteria from the wound bed to enable progression to the later phases of wound healing. Since the bacteria are cleared from the wound, the production of ROS and proteases is self-limited, minimizing bystander cellular damage. **B:** In a setting of regional hypoxia or other comorbidities, bacteria are not efficiently cleared, partly due to an ineffective oxidative burst, which requires oxygen. Bacteria will continue to accumulate in a biofilm state and a level of critical colonization or frank infection will result, leading to an amplified and/or prolonged inflammatory state with further tissue damage and persistent hypoxia as neovascularization is impaired. (Reproduced with permission from Thorne CM. *Grabb and Smith's Plastic Surgery*, 6th ed. Philadelphia, PA: Lippincott Williams & Wilkins; 2006, Figure 3.1.)

3-mm point in a matter of days in a loose-skinned animal. Humans, however, do not have this degree of skin mobility in most sites; the skin is tightly adherent and less elastic, particularly in the lower leg. Therefore, although contraction may account for 90% of the reduction in wound size on the perineum, it accounts for at most 30% to 40% of the healing of a lower leg ulcer. This is one important reason why leg ulcers are so slow to heal. All healing wounds generate a strong contractile force.⁹ When this contractile force is exerted across a joint, such as the neck, axilla, or elbow, it may result in a scar contracture. A scar contracture is a scar that limits the functional range of motion of a joint.

At the cellular level, the forces that drive wound contraction come from the fibroblasts. Fibroblasts, like muscle cells, contain actin microfilaments. When these filaments increase in number, the cells take on the morphologic appearance of myofibroblasts. Myofibroblasts are seen in increased numbers in contracting wounds, but their role and derivation are unclear. It is unknown whether the fibroblasts that attach to the collagen fibrils by means of integrin receptors move collagen fibers together using a locomotor action or whether the contraction comes from intrinsic cellular contraction, but it is likely that contraction is due to a combination of the two. In addition, it is still unclear whether myofibroblasts are derived from tissue-resident fibroblasts that phenotypically assume the role of a myofibroblast in response to tissue strain and molecular mediators such as TGF- β 1 or develop from blood-borne precursor cells such as fibrocytes that are recruited to an open wound. The forces of contraction continue as long as there is inflammation and collagen remodeling.

Unless created and dressed under sterile conditions, all open wounds are contaminated by the bacterial flora on the surrounding skin and from the environment. Even when dressed under sterile conditions, bacterial colonization will occur within about 48 hours from the surrounding skin. Bacterial *colonization* of the wound is routine and is not deleterious to normal healing. However, bacterial *infection*, defined as a bacterial presence that overwhelms the host response, is deleterious and can delay or prevent healing. Cellulitis or invasive bacterial infection of the surrounding skin is relatively easy to diagnose with experience. Treatment typically requires systemic antibiotic therapy. Distinguishing wound colonization from excess bacterial load resulting in excess inflammatory cells, protease degradation of matrix, and impaired healing, however, can be difficult. The burn wound experience has demonstrated that bacterial counts of more than 10^5 organisms per gram of tissue on quantitative analysis are associated with failure of surgical wound closure. This is an important technique, because clinical judgment is inadequate. The failure of wound closure in this circumstance is in part due to bacterial and phagocytic proteases that prevent healing. In a similar fashion, if the bacterial count is above this threshold in the wound granulation tissue, the endotoxins and excessive proteases, derived from both bacteria and PMNs, delay epithelialization. Several experimental systems have demonstrated that an excess of PMNs in a wound delays healing. Clinical experience with pilonidal wounds, with no other risk factors for impaired healing other than an increased bacterial burden, indicates that resolution of that one variable can result in rapid healing of wounds that have remained open for months or even years.

Any nonepithelialized wound leaks plasma. With more inflammation, capillary permeability is further increased. Increased microvascular permeability results from endothelial cell injury or dysfunction. This is mediated by many components of the inflammatory cascade, including histamine, kinins, complement, PGE₂, PGI₂, VEGF, and others. This exudate of serum proteins and inflammatory cells serves as a rich culture medium, which may continue the cycle of bacterial

proliferation and leads to more exudate formation. The net result of this cycle is delayed or absent wound healing. In addition, the edema that results from capillary dysfunction increases the distance for diffusion from oxygen and nutrient sources to their metabolic targets.

Clinical Features

Basic principles of wound care should be tailored to assist the mechanisms elaborated earlier, leading to more rapid healing. Although many varieties of wound care are practiced, Winter and Scales¹⁰ first recorded that epithelialization is more rapid under moist conditions than dry conditions. Without dressings, a superficial wound, or one with minimal devitalized tissue, forms a scab or crust. The scab forms when blood and serum coagulate, dry, and form a protective moisture barrier over the open wound (Fig. 4.7). Epithelialization occurs with controlled clot proteolysis and migration of the epithelium under the clot. If the wound is kept moist with an occlusive dressing, however, and the exudate does not become infected, then epithelial migration is optimized. A skin graft donor site, for example, epithelializes several days faster under an occlusive dressing than a dry dressing. In addition, the pain of an open wound or skin graft donor site is dramatically reduced under an occlusive dressing.

Moist healing can be achieved by occlusive dressings, ointments or creams, or continually moistened dressings. The traditional wet to dry dressing, however, if truly left to dry, simply produces desiccation and necrosis of the surface layer of the wound, delaying epithelialization. Although wet to dry dressings can be effective for débridement of wound exudate, they are generally less desirable than a moist healing environment combined with effective cleaning of the wound (i.e., water irrigation or a tailored surgical débridement).

Role of Oxygen

Oxygen is necessary for normal metabolic cellular function, but in wounds with actively proliferating and metabolically stimulated cells, it is even more critical. PMNs require ambient PO₂ levels of 25 mm Hg to produce superoxide radicals, which serve an essential role in bacterial killing. The enzyme system that generates superoxide and its derivative oxidant products functions optimally at PO₂ levels greater than 50 mm Hg. Collagen synthesis is also highly dependent on an adequate tissue oxygen tension. A fresh wound is initially avascular and is always hypoxic relative to the surrounding tissues. In the center of a new wound, the tissue PO₂ can drop to near zero. After angiogenesis and the delivery of oxygenated blood, the tissue PO₂ quickly rises. Generally, the tissue oxygen tension in a wound is lower than that of surrounding normal tissues. Atherosclerosis of major arteries, small vessel disease from other causes, impaired oxygen delivery, local scarring with fibrosis, and other events may reduce local tissue PO₂ levels from normal (about 40 mm Hg) to less than 25 mm Hg. If so, tissue hypoxia results in significantly impaired wound healing. In the postoperative patient, suboptimal skin perfusion due to even modest hypovolemia, smoking-related arteriopathy, or excess circulating epinephrine can result in a low tissue PO₂. Subcutaneous tissue oxygen levels have been correlated clinically with surgical complication rates. Supplemental oxygen, optimal fluid administration, pain control, and arterial reconstruction all have potential roles in the effort to enhance the tissue PO₂. Oxygen delivery to tissue is the primary determinant of healing; anemia alone is not specifically detrimental to wound healing.¹¹

FIGURE 4.7. Rapid epithelialization occurs in a moist environment. Desiccation delays healing by causing tissue necrosis in the exposed wound. The scab ultimately forms a moisture barrier, and epithelialization occurs from the wound edge and any remaining dermal appendages.

Hyperbaric oxygen therapy (HBO) can achieve high oxygen levels in most wounds for the duration of the treatment, usually 1.5 hours at a time. The patient is placed in the hyperbaric chamber and is exposed to 2 to 2.5 atmospheres of pressure and 100% oxygen. Although oxygen is a necessary component in aerobic metabolism, it may also act as a signaling molecule for growth factor production. There is extensive clinical experience suggesting clinical efficacy of HBO, but conclusive prospective randomized trials have not been conducted. It is clear that HBO can raise the PO_2 in ischemic wounds, but the indications, length of treatment, and number of treatments are still empiric. Based on the success of a number of retrospective studies, the usage of HBO in recent years has become widespread, particularly with diabetic foot ulcers and wounds that have been irradiated.

The role of oxygen as a therapeutic agent has been in part stimulated by an increased understanding of the role of oxygen in intracellular signaling. Previously, oxygen was thought to play an essential role in oxidative metabolism, but oxygen sensors were thought to be limited to the kidney (erythropoietin synthesis), the carotid body, and other specialized organs. However, there has been a great deal of interest, in recent years, in the existence in every cell of signal transduction pathways in response to hypoxia. These pathways are mediated by the master transcription factor HIF-1 that is transported to the nucleus and binds to the promoter region to activate synthesis of many genes including growth factors and hormones such as VEGF, erythropoietin, and stromal cell-derived factor (SDF). Therefore, there is a plausible role for intermittent oxygen therapy to induce signal transduction and improve wound healing. The amount of oxygen necessary to result in a therapeutic effect is unknown, but in the acute surgical situation there are data indicating a beneficial effect from supplemental oxygen in the immediate postoperative period. For the treatment of chronic wounds, placing the wound in an enriched oxygen environment has had some anecdotal interest.¹² Another

approach to increasing local tissue oxygenation is to increase blood flow. A number of studies have suggested that increasing local skin temperature has resulted in improved wound healing.

Role of Edema

In normal tissue, each cell is only a few cell diameters away from the nearest capillary and receives nutrients and oxygen by diffusion. However, with inflammation, venous insufficiency, or any other causes of edema formation, the sequestered extracellular and extravascular fluid increases the diffusion distance for oxygen and results in a lower tissue PO_2 . In the case of lower extremity venous insufficiency, the chronic protein leak from the capillaries results in pericapillary deposition. This “cuffing” is a further barrier to oxygen and nutrient diffusion and possibly functions as a site of nonspecific binding of growth factors, making them less available to the wound environment. The importance of edema control is often underestimated. Even in extremities that are not noticeably swollen, elevation and other methods of edema control (elastic wraps, compression stockings, and sequential compression machines) can be of substantial benefit. The most important therapeutic maneuver in the healing of leg ulcers associated with venous insufficiency is edema control with leg elevation, compression stockings or compressive dressings, and, in severe cases, intermittent or sequential compression devices.

Role of Tissue Necrosis and Exudate

Open wounds often contain devitalized tissue as a result of injury and may be aggravated by infection or suboptimal tissue perfusion. If the amount of dead tissue is large, the impairment to healing is obvious, but it is often not fully appreciated

that smaller amounts of necrotic tissue or fibrinous exudate also delay healing. In addition, any open wound constantly produces an exudate of serum proteins and dead inflammatory cells, which increases devitalized tissue, if present. The net result is increased exudate, higher bacterial counts, edema, more proteases and other inflammatory mediators, and a deleterious effect on healing. Therefore, devitalized tissue, especially dermis, generally requires surgical excision. If necrotic dermis is left in place, the underlying subcutaneous tissue (fat), which is less vascular, eventually becomes infected. Small amounts of devitalized tissue and exudate can be débrided or removed with dressings, enzyme application, whirlpools, water irrigation, or simple washing. However, the mechanical débriding action must be sufficient and frequent enough to remove the exudate and debris, producing a clean wound before healing is optimal. Because wounds are painful and the dressings or washings insufficient, the exudate is often not removed adequately. This results in delayed healing. The impact of water irrigation in cleaning a wound and reducing tissue bacterial counts has been underappreciated. Whirlpool can gently clean a wound and modestly reduce tissue bacteria counts, but water under pressure (pulse lavage, syringe irrigation with sufficient force, or even a shower stream or dental water pic) can reduce bacterial counts in tissue by several logs.

CHRONIC WOUNDS

- 6 A practical definition of a chronic wound is one that has failed to heal within 3 months. Although there are a variety of underlying causes, most chronic wounds can be categorized as pressure sores, diabetic foot ulcers, or leg ulcers. An important question is whether chronic wounds are intrinsically different than acute wounds. For instance, does local tissue senescence make healing a chronic wound impossible? Or do chronic wounds have the inherent potential to heal, but a combination of factors leads to delayed healing? Research in the past few years has begun to address the question of what is different about the environment in a chronic wound. One important realization is that most chronic, nonhealing wounds are characterized by the presence of three variables: advanced age, local tissue ischemia with reperfusion injury, and excess bacterial load.¹³

Clinicians have long recognized that most chronic wounds do indeed have the potential to heal. Healing usually does not occur because of inadequate attention to the basic principles of open wound care—adequate cleansing, débridement, edema control, avoidance and treatment of ischemia, and achievement of a moist wound healing environment. However, the wound environment in many chronic wounds does differ in important ways from acute wounds. Studies have examined wound fluid and biopsies collected from chronic wounds. These reveal significant increases in tissue levels in proteases and collagenases, which are capable of degrading matrix proteins and growth factors. Degradation of growth factors inhibits their crucial functions of proliferation and chemotaxis. When wound fluid from a chronic wound is compared with fluid from an acute surgical wound, there is indeed a decreased level of growth factors. It is not clear what influence bacteria have in this process, although the direct release of bacterial proteases and the indirect effect of protease release from phagocytic cells are both relevant. It is unknown whether growth factor levels are depressed because of proteolysis, primary inhibition of release, or secondary phenotypic changes in the cells of the chronic wound.

Another important factor in the genesis of chronic wounds is the fact that their occurrence is generally in the aged, who have an impaired response to the stress factors of local tissue hypoxia, the increase in reactive oxygen species generated by inflammatory cells, and the existing bacterial burden. As mentioned previously, most chronic wounds are of three types: pressure sores, diabetic foot ulcers, and venous leg ulcers. In

all three types, the inciting injury is an ischemia reperfusion injury. In the first two types, pressure exceeding tissue perfusion resulting in a period of ischemia is followed by reperfusion. Repeated cycles of ischemia and reperfusion are much more damaging than an ischemic insult by itself. Experimental evidence in animals supports the notion of an increase in tissue damage in response to an ischemia reperfusion injury.¹³

In chronic wounds, there is some evidence that cells in the periphery of the wound can become senescent after the prolonged stimulus of many months. This is likely a more problematic factor in the elderly and provides a theoretical basis for the efficacy of surgical débridement and excision of the “rind” or callus of a chronic wound, converting it to an acute wound and converting a nonhealing wound to a healing wound.

The final common denominator in the triad of factors that is present in most chronic wounds is excess bacterial presence. It has recently become appreciated that bacteria exist in wounds in the setting of a biofilm.¹⁴ Biofilms represent a complex community of bacteria that are present within a secreted and assembled exopolysaccharide matrix. They interact with each other via the process of quorum sensing. The slime layer in which they encase themselves protects them from the inflammatory cells of the wound. In a wound that has reached critical colonization, the robust inflammatory process necessary for bacterial clearance actually becomes a deleterious process. The overproduction of free radicals and proteases serves to divert resources and nutrients away from the healing cells and results in significant bystander damage. This is of importance in a debilitated or elderly patient. As mentioned, the hostile wound environment and altered pH can degrade or inactivate growth factors to further impair healing. The presence of this leads to further tissue damage, eventually resulting in a vicious cycle of tissue injury, bacterial overgrowth, and further tissue injury in the form of bystander damage as the body’s inflammatory cascade becomes unregulated (Fig. 4.6). Clearance of bacteria via a surgical débridement will break this cycle, reduce the inflammatory cascade, and allow progression of the wound through the appropriate stages of wound healing.

WOUND MANAGEMENT

Surgical Incisions

- 8 It takes at least 3 weeks for collagen to undergo sufficient remodeling and cross-linking to attain moderate strength. Figure 4.4 shows that at 1 to 2 weeks, the time when most sutures are removed, a wound has a small fraction of its eventual strength and may therefore disrupt with even modest stresses. Therefore, deep sutures are placed in collagen-containing structures to hold prolonged tension. Dermis, intestinal submucosa, muscular fascia, tendon, ligament, Scarpa fascia, and blood vessel wall represent a partial list of tissues with high collagen content. These deep sutures are often absorbable. The most common absorbable material, polyglactic acid (Vicryl, Dexon), retains tensile strength for about 3 weeks. Sutures used for tendon and abdominal fascia are usually permanent or, if absorbable, should ideally retain their tensile strength for close to 6 weeks. After 6 weeks, wounded tissue has gained about 50% of its eventual strength. To prevent hernia formation, heavy lifting is avoided after major abdominal surgery for 6 weeks. Tendon repairs are splinted and activity restricted to avoid full tension for a similar period.

As discussed in earlier sections, the fibroblasts in a wound respond to mechanical forces, and because skin has elastin fibers and tends to retract in response to injury, virtually all wounds are closed under some tension. If the tension forces are relatively large (in excisional wounds, for instance), sutures that effectively splint the wound, preventing the wound fibroblasts

from experiencing large mechanical forces, will result in less collagen excess (scar hypertrophy) and less scar stretch. Most absorbable sutures retain their tensile strength for only 3 weeks or so. Studies in humans have demonstrated that this is insufficient to prevent scar widening and results in no better scars than those in which all sutures are removed at 7 days. Therefore, to achieve optimal scars in wounds closed under tension or in areas such as the shoulder, permanent sutures should be left in place for 6 months until collagen remodeling is essentially complete. A continuous intradermal Prolene suture or intradermal interrupted clear nylon sutures with buried knots will achieve that objective.

Open Wound Dressings

There are at least 150 dressing products commercially available at present. These include multiple topical antibiotics, irrigants, and debriding agents. Although PDGF (Regranex) and tissue engineered living cell constructs (Apligraf and Derma-graft) have been shown to decrease healing times in certain wounds, standard treatment, which adheres to the principles outlined earlier, may be successfully applied to the vast majority of wounds. There are many good alternative treatments, but to avoid confusion, they should be judged according to the following criteria:

1. How effectively is the wound cleaned or debrided?
2. Is moist wound healing achieved?
3. Is edema minimized in the periwound tissue?
4. Are new pressure (ischemia reperfusion) insults or wound soilage prevented?
5. Is tissue oxygenation (blood flow) adequate?

In some situations, reduction of tissue bacteria is also an important additional need; this is most often addressed by adequate cleaning and débridement. In the absence of large amounts of necrotic tissue, wound débridement does not need to be accomplished surgically. Proteinaceous exudate can be tenacious, however, and simple application of moist dressings may not be adequate to remove it. Water irrigation either in whirlpools or by water from a handheld shower spray or even from dental water cleaning devices can be gentle and yet generate enough power to effectively débride.¹⁵ Frequent moist dressing changes can accomplish this as well, and in some cases, occlusive absorptive dressings can generate enough tissue proteases to effectively degrade proteins that the absorptive dressings remove (autolytic débridement). This deceptively simple principle is the most frequently overlooked in wound care. The typical open surgical wound often contains deep interstices that packing or other absorptive dressings may not effectively reach. The deeper portions of the wound may then accumulate exudate and bacteria. This is one example in which water irrigation may be particularly useful. Commonly used agents such as hydrogen peroxide are actually harmful to normal tissue and are weak oxidants and thus do a poor job of débriding. These are to be avoided. Enzymatic débriding agents can be effective when properly used.

As discussed, a desiccated wound undergoes delayed healing. Most wounds require an absorptive dressing to remove exudate. This can be gauze, which is inexpensive and effective but which requires frequent dressing changes and is not occlusive so that an ointment or cream must be added. Skin graft donor sites do well with an occlusive polyurethane film dressing. Most of the newer dressing products have been designed to be more absorptive and achieve moist healing without infection from excess exudate. An emphasis has been placed to decrease the frequency of dressing changes. It must be emphasized that although factors such as convenience, patient acceptance, and cost are good reasons for choosing a product, as long as moist healing is achieved, there is no evidence that one is better than another.

Edema is detrimental to wound healing and is often under-treated, in part because of difficulties in patient education. Edema can be a factor in virtually any ulcer of the lower extremity, although venous insufficiency is the most important. Because patients often have personal habits that are hard to modify, this can be a refractory problem. Patients often object to compression stockings, the most effective method for limiting edema. This leaves intermittent leg elevation, elastic wraps, and elevation of the foot of the bed as alternative measures. The critical factor is getting the patient to realize that leg swelling must be avoided, and so in the course of the day, each patient must modify behavior sufficiently to treat this problem.

Systemic Factors Affecting Wound Healing

Several important systemic factors or conditions influence wound healing. Interestingly, there are no known systemic conditions that lead to more rapid wound healing. The discussion that follows relates to factors that may retard or inhibit wound healing.

Nutrition. Wound healing requires energy and is an anabolic process. Patients who are severely malnourished or who are actively catabolic demonstrate impaired healing. Although there is no single measure of nutritional adequacy, the serum albumin level is the most readily available and clinically useful parameter. A serum albumin greater than 3.5 g/dL suggests adequate protein stores and positive nitrogen balance. However, albumin has a serum half-life of 19 days. Therefore, the serum albumin level does not drop early in a catabolic process and is slow to rise when protein stores are depleted and an anabolic state returns. Serum transferrin has a shorter half-life and, therefore, responds more promptly to nutritional fluctuations, but it is not part of a routine chemistry panel and has not gained widespread clinical usage. There is no consensus on nutritional parameters that accurately predict the development of surgical complications. In considering closure of a chronic wound such as a pressure sore, the ability to form granulation tissue and begin wound contraction are clinical indications of acceptable wound healing potential. The presence of a granulating, contracting wound argues strongly that the patient has adequate nutrition to undergo surgery. An albumin level of less than 3 mg/dL raises concern for potential wound healing problems. In clinical practice, the trajectory of prealbumin levels (i.e., an increased level measured weekly) may be more useful than a static level and suggests the restoration of adequate stores. Most surgeons avoid trying to close chronic wounds surgically until nutritional levels are considered acceptable, particularly in the elderly.

Vitamins play an important role in wound healing as well. Vitamin A is involved in the stimulation of fibroplasia, collagen cross-linking, and epithelialization. In animal studies, vitamin A reverses the inhibitory effects of glucocorticoids on the inflammatory phase of wound healing.¹⁶ Although there is no conclusive evidence in humans, vitamin A may be useful clinically for steroid-dependent patients who have problematic wounds or who are undergoing an extensive surgical procedure. Vitamin A may be used either topically or systemically, but attention should be paid to the dosage and duration of therapy as vitamin A is fat soluble and has a well-defined toxicity state. An oral dose of 25,000 IU daily or topical application of 200,000 IU ointment three times a day should be sufficient.

Vitamin C is a necessary cofactor in the hydroxylation of lysine and proline in collagen synthesis and cross-linkage. The deficiency state, scurvy, is rarely seen in the Western world today. The utility of vitamin C supplementation in patients who are taking a normal diet is not established.

Vitamin E is applied to wounds and incisions by many patients. The evidence to support this practice is entirely anecdotal, and, in fact, large doses of vitamin E have been found to inhibit wound healing.¹⁷ Only massage, pressure, and silicone

sheeting have been shown to flatten and soften scars. Many people perceive a healing benefit from topical creams, but it is very difficult to exclude the two main variables in scar formation: (a) scars improve with passage of time and (b) there is natural variability in scar formation between different individuals and in the same individual in different locations and at different ages.

Essential fatty acids are required for all new cell synthesis. Essential fatty acid deficiency is first noted in areas of high cellular turnover, such as healing wounds, skin, and gastrointestinal mucosa. Early experience with total parenteral nutrition in which essential fatty acids were lacking showed that patients developed difficult wounds and dramatic skin changes. These were rapidly reversed with the addition of fat to the parenteral nutritional program.

Zinc and copper are also important cofactors for many enzyme systems that are important to wound healing. Deficiency states have been seen with parenteral nutrition but are rare and now readily recognized and treated with supplements.

Vitamin and mineral deficiency states clearly show the necessity of these agents for wound healing. However, these deficiency states are extremely rare in the absence of parenteral nutrition or other extreme dietary restrictions. There is no evidence to support the concept that supranormal provision of these factors enhances wound healing in normal patients. Significant complications, especially with excessive fat-soluble vitamin supplementation, are reported. However, malnutrition can be a significant problem in the elderly and debilitated patient. These patients require nutritional supplementation and should receive vitamin and mineral supplementation as part of their protein and caloric repletion.

Aging. There are important age-dependent aspects of wound healing. The elderly heal more slowly and with less scarring. There is gradual attenuation of the inflammatory response with age, and decreased wound healing is one of the consequences. In vitro studies have documented an age-dependent decrease in the proliferative potential of fibroblasts and epithelial cells. Clinically, these account for the formation of finer scars and improved cosmetic appearance in the elderly. Hypertrophic scars are rarely seen in the elderly. Sutures should be left in place longer to allow for the slower gain in tensile strength in the aged. This may be done without formation of suture marks as slower epithelialization occurs along the sutures. Although the aged usually heal from surgical incisions without complications, the combination of age and other adverse factors can result in severe healing deficits and high surgical complication rates (see the previous section on chronic wounds).

Pharmacologic Impairment to Wound Healing. Bone marrow suppression, a common consequence of chemotherapy, is detrimental to wound healing. Quantitative and qualitative lymphocyte and monocyte deficiency impairs cellular proliferation in the inflammatory phase of wound healing. Any chemotherapeutic agent that suppresses the bone marrow will impair healing. Fortunately, this is predictably reversible with cessation of chemotherapy. Glucocorticoids inhibit wound healing based on their anti-inflammatory and immunosuppressive effects. The anti-inflammatory effect of steroids is in part the result of inhibiting arachidonic acid metabolism, resulting in impaired macrophage migration and altered neutrophil function. Glucocorticoids also inhibit synthesis of procollagen by fibroblasts, delaying wound contraction. Steroid-dependent patients have a persistent decrease in wound tensile strength even after healing is complete. Patients who require chronic systemic steroids have attenuation of the dermis and are therefore susceptible to injury. Even minor shearing forces may produce tearing of the skin and full-thickness wounds due to the decreased tensile strength. The advent of antiangiogenic agents in the treatment of cancer unfortunately also contributes to impaired wound healing. Agents such as bevacizumab and

TABLE 4.3**FACTORS THAT CONTRIBUTE TO WOUND ISCHEMIA**

Smoking
Radiation
Edema
Diabetes mellitus—accelerates atherosclerosis, microvascular dysfunction
Vasculitis
Fibrosis—chronic scarring
Pressure—pressure sores or decubitus ulcer

sunitinib impair angiogenic growth factors such as VEGF. Since wound healing is an angiogenesis-dependent process, particularly recalcitrant wounds can result from use of these medications.

Ischemia. Adequate tissue oxygenation plays a critical role in wound healing.¹⁸ Oxygen is needed for aerobic metabolism and also for proper neutrophil function, especially in bacterial killing. Oxygen is also a requirement for hydroxylation of proline and lysine to form stable collagen fibrils (Table 4.3).

Smoking. Smoking or nicotine patches inhibit oxygen delivery via sympathomimetic vasoconstriction. In addition, smoking elevates carboxyhemoglobin levels in the blood. This effect shifts the oxygen delivery curve to the left due to the high affinity of carboxyhemoglobin for oxygen, resulting in less available oxygen in the wound. Animal studies demonstrate that even moderate decreases in tissue oxygen tension result in severe impairment of wound healing with substantially increased infection rates. Smoking has been shown to increase wound complication rates when skin flaps are elevated with marginal distal blood supply.

Radiation. Radiation injury leads to arteriolar fibrosis and impaired oxygen delivery. In addition, there is progressive obliteration of blood vessels in the radiated area over time. Radiation also causes intranuclear and cytoplasmic damage to fibroblasts, and this change appears to limit their proliferative potential. It is important to realize that radiated tissues gradually and progressively deteriorate over time. Irradiated wounds will often require a flap (i.e., the introduction of healthy nonirradiated tissue) for successful closure.

Edema. Edema impairs local oxygen delivery. In addition, edema is often associated with increased venous pressure. This postcapillary obstruction decreases the perfusion pressure in the capillary bed, resulting in ischemia. Increased venous pressure also leads to protein extravasation and pericapillary cuffing. This effect acts as a diffusion barrier to oxygen, further impairing tissue oxygenation and wound healing.

Diabetes. Diabetes mellitus is often associated with decreased healing of open wounds and increased susceptibility to infection. Many factors contribute to poor healing in diabetic patients, and most of these reflect local wound ischemia. However, healing is not impaired in a normally perfused area in a patient with well-controlled diabetes in the absence of infection. This subject is discussed in detail later.

Neuropathy. There is considerable evidence that neuropeptides promote healing, and their decrease or absence in the

setting of spinal cord injury is a factor in impaired wound healing and may be a factor in the neuropathy of diabetes. This is not currently a condition that can be treated effectively, although the neuropeptides that impact wound healing are a focus of active research.

Other Local Conditions. Peripheral arterial occlusive disease secondary to atherosclerosis can be a primary cause of impaired healing and may also be a cofactor with the other conditions discussed. In addition, conditions such as vasculitis, prolonged pressure, lower leg venous insufficiency, and tissue fibrosis affect wound healing through the mechanism of local tissue ischemia.

Chronic Wound Care

A chronic wound is commonly defined as an open wound that has failed to respond to standard care and remains open at 3 months. Typically, the wound size is static with an absence of a visible advancing epithelial edge. The etiology of a chronic wound is often multifactorial. One or more factors that impair wound healing, such as advanced age, ischemia, bacterial contamination, edema, and malnutrition or immunosuppression, are often present in patients with chronic wounds. A systematic approach is needed to identify the causative factor(s). Once all of the potentially applicable factors have been identified, those amenable to treatment should be addressed. Although age is fixed, some impact can be made on most other factors. Wounds should be débrided, and topical as well as systemic antibiotics may be indicated for true bacterial infection. Arterial revascularization can increase oxygenation in the wound, and elevation and compression dressings can decrease edema. Skin grafting or other surgical procedures are indicated as long as the underlying processes have been identified and appropriately treated. The underlying causes of some chronic wounds cannot be corrected in some patients, such as those with diabetes or venous insufficiency. Specific chronic wounds are discussed in the sections that follow.

Pressure Sores. Pressure sores are sometimes mistakenly referred to as bed sores or decubitus ulcers (Fig. 4.8). These sores do not always develop in bed or while lying flat in a decubitus position. All pressure sores, regardless of location, do involve prolonged pressure over a bony prominence followed by reperfusion, which produces much of the injury, particularly when there are repeated cycles. The ability of tissue to withstand pressure is defined by the duration of the pressure, the amount of pressure, and related shear forces. The most frequent locations of pressure sores are overlying the ischium, sacrum, and trochanter. The heel, knee, ankle, and posterior scalp are less common locations.

Prolonged pressure produces ischemia in the tissue by occluding the microcirculation. This occurs when the tissue pressure exceeds the capillary filling pressure of 25 mm Hg. Pressure on the tissue overlying the sacrum can reach 80 mm Hg in a recumbent patient, so that tissue necrosis can occur within hours if not relieved by frequent changes in position.

Skin is more resistant to pressure than is the underlying subcutaneous fat (which has less blood supply) or muscle (which, although having an excellent blood supply, is very sensitive to ischemia). This sensitivity accounts for the common finding of a small skin ulceration overlying a large area of subcutaneous necrosis. Efforts to identify and control factors that contribute to impaired wound healing should be made. Nutrition is often a problem as is bacterial overgrowth. If the patient can avoid pressure on the involved area and other contributing factors are controlled, most pressure sores will heal. There is a higher incidence of recurrence if pressure sores are allowed to heal by secondary intention rather than by surgical closure. This difference is explained by the increased scarring

FIGURE 4.8. Pressure ulcer staging. A: Stage I—erythema. B: Stage II—breakdown of the dermis. C: Stage III—full-thickness skin breakdown. D: Stage IV—bone, muscle, and supporting tissue involved. (Reproduced with permission from Nettina SM. *The Lippincott Manual of Nursing Practice*, 7th ed. Philadelphia, PA: Lippincott Williams & Wilkins; 2001.)

that occurs with healing by secondary intention and the fact that this places the scar directly over the pressure point. Because scars are never as strong as intact skin, they are more prone to breakdown than intact skin that has been placed over these pressure points by surgical closure. Patients with significant life expectancy, such as young paraplegics who have a precipitating factor leading to development of a pressure sore, are best treated with surgical flap closure. The recurrence rate can be as high as 90% if chronic issues such as depression are not adequately treated (leading to neglect).

Leg Ulcers. Leg ulcers are perhaps the most common type of chronic ulcer. The underlying disease process is most often local tissue ischemia. The underlying cause of this local tissue ischemia should be identified and appropriate treatment initiated. About 90% of leg ulcers in the United States are secondary to venous insufficiency (valvular incompetence) (Fig. 4.9). Venous ulcers lead to local tissue ischemia by increased venous pressure, which lowers the transcapillary perfusion pressure, and by leg edema. Initial treatment should be directed to cleansing and débriding the wound of proteinaceous exudate and limiting the edema and protein loss with compression dressings and elevation. A common treatment has been the Unna boot, a paste bandage that is absorptive, limits edema, and can be changed weekly. This allows the physician to control treatment with weekly visits. If this dressing is made compressive by adding an elastic wrap, it is highly effective in reducing edema, absorbing exudate, and providing an occlusive wound environment. Its limitations are that it requires weekly visits and precludes normal showering or bathing. Another alternative that has become standard in many venous leg ulcer studies is the four-layered compression garment, in which multiple layers result in effective compression over many days. With effective compression, over 50% of venous ulcers can be healed within a 3- to 4-month period. Compression garments or elastic wraps with frequent dressing changes, thorough cleaning, and an occlusive dressing can be equally

FIGURE 4.9. Venous ulcer. (Reproduced with permission from Nettina SM. *The Lippincott Manual of Nursing Practice*, 7th ed. Philadelphia, PA: Lippincott Williams & Wilkins; 2001.)

effective. Surgical treatment of venous insufficiency is addressed elsewhere and is useful only in isolated instances in which an incompetent perforator can be identified proximal to an ulcer. Valve reconstruction has not achieved widespread acceptance in the United States.

Additional causes of leg ulcers include arterial insufficiency and other vasculitis syndromes. These are treated best by correcting the underlying disease and local wound care. If the underlying problem cannot be treated, there is little hope of securing a stable, healed wound. For example, vasculitic ulcers will often heal with the judicious use of steroids.

Diabetic Foot Ulcers. Diabetic foot ulcers are caused by pressure over bony prominences, usually the metatarsal heads or calcaneus, in the setting of neuropathy (Fig. 4.10). There is, however, no evidence to support the often-cited concept that these ulcers may result from small vessel disease. This theory originated with a nonblinded study of the microvasculature in amputation specimens by Goldenberg in 1959. Subsequent blinded studies have failed to reveal any architectural differences in small blood vessels of diabetic amputation specimens. However, there is evidence that there may be a *functional* microangiopathy in diabetic patients, with impairments in vasodilatation and angiogenesis after injury. The ischemia in diabetic foot ulcers is due to prolonged pressure on insensate toes and feet, with subsequent reperfusion. This pressure ischemia is enhanced by the increase in blood viscosity related to nondeforming erythrocytes, which develop because of nonenzymatic glycosylation of cell membrane proteins. These rigid red blood cells plug capillary beds and decrease microvascular flow. In addition, glycosylated hemoglobin has increased affinity for oxygen, thereby making less oxygen available to the tissues. Diabetic patients also have a predilection for infrapopliteal arterial occlusive disease and may therefore benefit from arterial reconstructive surgery. The requirements for successful treatment of diabetic ulcers include pressure relief with non-weight-bearing strategies and aggressive débridement of callus and marginally vascularized wound edges. Preventive measures with appropriate orthotic shoes are essential once healing is achieved. It should be remembered that it is in

FIGURE 4.10. Diabetic ulcer of the heel. These lesions are noted at sites of pressure, such as the heel in this patient. (Reproduced with permission from Goodheart HP. *Goodheart's Photoguide of Common Skin Disorders*, 2nd ed. Philadelphia, PA: Lippincott Williams & Wilkins; 2003.)

clean diabetic forefoot wounds that the clinical effectiveness of becaplermin gel has been demonstrated.

Diabetic foot ulcers are best treated in a multidisciplinary clinic with a combination of surgical and adjunctive measures. If vascular studies indicate significant underlying disease and reduced toe pressures, the leg should be revascularized if possible. Often, diabetics develop altered pressures on their metatarsals and midfoot secondary to neuropathy and loss of functioning intrinsic muscles in the foot. The Achilles tendon can also shorten due to the buildup of glycosylated end products within the matrix-rich tendon. In addition to orthotics, surgical procedures to partially correct the altered pressure patterns such as Achilles tendon lengthening can be beneficial. Aggressive surgical débridement to remove callus and convert the chronic wound to a well-vascularized acute wound can be therapeutic. Becaplermin gel has been most efficacious in the setting of aggressive serial débridements.

Agents to Optimize Wound Healing

Dressings. Becaplermin gel has been shown to speed healing in diabetic forefoot wounds and probably has a role in other chronic wounds for which there is a paucity of pharmacologic agents. The biologic dressings Apligraf and Dermagraft have been approved for use in venous ulcers and diabetic ulcers, respectively, and some clinicians feel they play a role in recalcitrant wounds. Many types of dressings are commercially available, and none have been demonstrated to be effective if standard care is ignored. Despite marketing claims, standard wound care, keeping wounds clean, moist, and as free of edema and bacteria as possible, are still the most important factors in ensuring wound healing.

The ideal dressing should be simple, inexpensive, highly absorptive, and nonadherent. It should achieve moist healing and have antibacterial properties. Other factors to be considered are less frequent dressing changes, an all-in-one dressing that does not require tape or an overlay, and a gentle adhesive that is effective but not injurious to the skin when removed.¹⁹

The simplest dressing is gauze and tape—it is inexpensive, is absorptive, and when used with an ointment, can achieve moist healing. The primary disadvantages are the necessity for frequent dressing changes and the potential for tape irritation

and wound desiccation. Other products are classified into films, foams, hydrocolloids, hydrogels, and absorptive powders (Table 4.4). Films are semipermeable to water, generally made of polyurethane, and nonabsorptive. These are useful to achieve a moist wound healing environment over minimally exudative wounds, such as a split-thickness skin graft donor site.

Other dressing types have been designed to increase the absorptive capacity of the dressing. This requires fewer dressing changes and maintains an environment for moist healing.

The hydrocolloids deserve special mention because they have achieved widespread use. These contain hydrophilic materials, such as guar, karaya, gelatin, or carboxymethylcellulose, with an adhesive material and are covered by a semipermeable polyurethane film. The material adheres to the skin surrounding the wound, is highly absorptive, and achieves a moist healing environment. Adhesion is maintained until the absorptive capacity is exhausted, and then atraumatic removal is easily done. Similar materials have been extensively used for peristomal care. These are best used for open wounds that have only moderate exudate.

The increased absorptive capacity of these products allows infrequent, minimally traumatic dressing changes. This, along with ease of use and achievement of moist healing, are their principal advantages. Although the availability of these dressing products is accelerating at a dizzying pace, the overriding principle in the proper choice of a dressing is choosing one that will allow the optimal moisture balance within the wound. More exudative wounds will require a more absorptive dressing, whereas drier wounds (such as an arterial ulcer) will require a dressing regimen that gently hydrates the wound.

Antibiotics. The role of antibiotics in wound care is controversial. All open wounds are colonized with bacteria. Only when the surrounding tissue is invaded (cellulitis) are systemic antibiotics clearly indicated. Antibiotics may be useful in other situations, such as when the granulation tissue has a high bacterial count or in a case of reduced resistance to bacteria, such as in a diabetic foot ulcer, but these situations are not clearly defined. The routine use of systemic antibiotics for chronic wounds should be avoided to reduce the development of resistant bacterial strains within the wound.

Topical antibiotics are frequently used and can be useful. The ointment vehicle may help keep the wound moist, and the bacteria count in a wound may be lowered as a result. With most antibiotics, however, resistant organisms emerge quickly and development of allergic, hypersensitivity reactions are common. Most topical antibiotic ointments should be limited to 3 weeks of therapy to avoid developing a rash or other signs of inflammation as a result of the antibiotic ointment, not bacteria. The expense is substantial, and the benefits are not well demonstrated. Silver sulfadiazine, frequently used for burn care, is also useful for chronic wounds. Its broad spectrum of activity, the lack of relevant drug-resistant plasmids in bacteria, and its low cost make it a good choice.

In recent years, silver-impregnated dressings have become available and achieved widespread acceptance. They have the antibacterial activity of silver ions without the potential for allergy with sulfadiazine, combine a powerful broad-spectrum antibacterial activity without the problems of drug resistance, and have the absorptive activities of many dressings. However, although widely used, questions such as the concentration of silver needed for efficacy await better evidence before their routine use can be justified.

Débriding Agents. Collagenases have been used to débride wounds for 20 years and can be a highly effective adjunct in the treatment of chronic wounds with necrotic tissue. These agents may be used after surgical débridement to help clean a wound and to avoid a painful mechanical débridement. Currently, only one enzymatic agent is approved for reimbursement in the United States. Another method of wound débridement involves

the use of medicinal maggots (biologic débridement). Maggots are effective débridement agents that selectively digest nonviable tissue and also secrete bioactive compounds in their secretions that likely impair bacterial growth.

Pharmacologic Agents. Growth factors found naturally in wounds have improved healing in both normal and complex animal wounds. The growth factors with the most evidence for efficacy are PDGF, TGF- β , epidermal growth factor, and members of the FGF family, although IGF-1, interleukin (IL)-1, IL-2, granulocyte-macrophage colony-stimulating factor, and VEGF have also shown improved rates of healing in animal models.^{20,21} Clinical trials are in progress, and only becaplermin (PDGF) has been approved by the FDA. PDGF has shown efficacy in accelerating healing for patients with clean, well-vascularized diabetic forefoot ulcers. A limiting factor in these clinical trials has been the variability in patients in terms of both systemic factors that impact healing and the number of variables related specifically to the wounds. The clinical studies are therefore difficult to perform and interpret.

Growth hormone deserves brief mention because it has been used successfully in some situations to reverse the catabolic impact of many severe injuries. Wound healing is a fundamentally anabolic event (creating new tissue), and in the setting of a severe burn, growth hormone administration significantly accelerates donor site healing, presumably because of its effects in minimizing catabolism.

Negative-pressure Wound Therapy. In recent years, negative-pressure wound therapy (NPWT) such as the vacuum-assisted closure (VAC) device has gained increasing acceptance for a wide variety of difficult wounds. This treatment involves the application of a moderate vacuum to an occlusive dressing with a sponge or gauze to allow wicking of the exudates up into the dressing and out of the wound. On theoretical grounds, NPWT is an optimal wound therapy. The negative pressure results in reduction of wound edema and a resulting increase in local tissue perfusion. Continual removal of wound exudates removes the media for bacterial growth and results in removal of the bacteria as well, with a resulting reduction in bacterial burden, and the negative pressure accelerates wound contraction. At the cellular level, the microdeformation placed in cells in the wound bed is thought to upregulate the production of growth factors. NPWT has found uses in the treatment of chronic wounds and difficult acute wounds; for adherence of skin grafts; and, in recent years, in the treatment of open sternotomy wounds and exposed joint prostheses, as well as a variety of other applications. Often, use of NPWT has allowed secondary closure with a skin graft or straightforward secondary closure rather than a complex flap.^{22,23}

EXCESSIVE SCARRING

Many factors are involved in the formation of an ideal scar. The most important of these are (a) accurate alignment of sharply incised tissue parallel to the natural lines of resting skin tension, (b) closure of the wound without tension on the epidermis and without underlying dead space, and (c) primary healing without complications such as infection or dehiscence. The patient's genetic makeup and the location of the wound on the body are also important factors. The more negative factors that are associated with a particular wound, the more likely it will form a scar that is less than ideal. In general terms, the three main factors associated with an adverse scar include genetic predisposition, tension, and inflammation. From an evolutionary viewpoint, wound healing has been programmed to be rapid and exuberant to minimize the problems of an open wound. As part of the aging process, the proliferative phase of wound healing becomes less exuberant, and although wound healing is slower, scars are improved (see the remodeling phase

TABLE 4.4**WOUND DRESSINGS**

■ CLASSIFICATION	■ COMPOSITION	■ INDICATIONS	■ FUNCTIONS	■ EXAMPLES
Films	Semiocclusive (semipermeable)—polyurethane or copolyester	Acute partial- or full-thickness wounds with minimal exudate Nondraining primarily closed wounds	Mimics skin performance Is water vapor permeable Is water and bacterial impermeable Is retention dressing for gel Is retention dressing for tubes Provides moist environment	Op-site Bioclusive Tegaderm Blisterfilm Visulin
Hydrocolloids	Contain hydrophilic colloidal particles (quar, karaya, gelatin, carboxymethyl cellulose) in an adhesive mass (usually polysorbethylene)	Acute or chronic partial- or full-thickness wounds Stage I to IV decubitus ulcers	Absorbs fluid Débrides soft necrotic tissue by autolysis Protects wounds Provides good adhesiveness without adherence to wound Encourages granulation Promotes reepithelialization Protects wounds from trauma	Cutinova Hydro Duoderm Comfeel Restore Intrasite Ultec J&J ulcer dressing
Hydrogels	Contain 80%–99% water Cross-linked polymer such as polyethyleneoxide, polyvinyl pyrrolidone, or acrylamide	Acute or chronic partial-thickness wounds with minimal exudate	Creates moist environment Usually requires secondary dressing Has low absorbency Débrides minimally Decreases pain Does not adhere to wound	Vigilon Geliperm Elastogel Intrasite gel
Foams	Either hydrophilic or hydrophobic Nonocclusive Usually polyurethane or gel film coated High absorbency	Acute or chronic partial-thickness wounds that are highly secreting and require mechanical débriding	Débrides Has high absorbency Water vapor permeable	Cutinova Plus Lyof foam Allevyn
Impregnates	Fine-mesh gauze impregnated with moisturizing, antibacterial, or bactericidal compounds Nonadherent	Acute or chronic partial-thickness wounds with minimal or moderate exudate	Does not adhere to wound Promotes reepithelialization	Aquaphor-Gauze Adaptic Biobrane
Absorptive powders and pastes	Consist of starch, copolymers, or colloidal hydrophilic particles Can absorb up to 100 times their weight in fluid	Chronic full-thickness wounds with large amounts of exudate	Has high absorbency Débrides necrotic and fibrous material from wound	Spand-Gel Geliperm Envisan paste Bard absorption Dressing Duoderm granules Hydrogran Hollister Exudate Absorber

section). The distinctions between an unsightly scar, a hypertrophic scar, and a true keloid can be confusing. An accurate diagnosis of most scars can be made by clinical observation and the history of the lesion.

Keloids

9

True keloids are uncommon and occur predominantly in dark-skinned people with a genetic predisposition for keloid formation.⁷ In most cases, the gene appears to be transmitted in an autosomal dominant pattern. The primary difference between a keloid and a hypertrophic scar is that a keloid extends beyond the boundary of the original tissue injury. It behaves as a benign tumor and extends into or invades the normal surrounding tissue. This creates a scar that is larger than the original wound (Fig. 4.11).

Histologically, keloids contain an overabundance of collagen. The absolute number of fibroblasts is not increased, but the production of collagen continually outpaces the activity of collagenase, resulting in a scar of ever-increasing dimensions. The cause of keloid formation is unknown. Immunoglobulin G levels are increased, which suggests possible autoimmune stimulation resulting in a chronic inflammatory response with continued collagen deposition.

The treatment of keloids is difficult. The cause of keloids is unknown, and the underlying disorder is not resolved by any specific therapy. Some improvement is usually seen with excision followed by intralesional steroid injection.²⁴ In unresponsive cases, excision followed by a short course of radiotherapy has been successful, but the resulting scar is unpredictable and may potentially be worse. Keloids typically develop several months after injury and rarely, if ever, subside. Although many therapies have been tried, with anecdotal reports of success, none is ideal, and recurrence is frustratingly common.²⁵

Hypertrophic Scars

Hypertrophic scars are histologically similar to keloids. They contain an overabundance of dermal collagen. Hypertrophic scars, however, respect the boundaries of the original injury and do not extend into normal unwounded tissue. They have less genetic predisposition, but hypertrophic scars also occur more frequently in Asian and African skin. They are often seen on the upper torso and across flexor surfaces. They usually

develop within the first month after wounding and often subside gradually (Fig. 4.12).

Improvement of hypertrophic scars may be obtained with pressure garments, topical silicone gel sheeting applications, or reexcision and closure.^{6,26} Reexcision and closure should be considered if conditions of the closure can be improved. This is especially true for wounds that originally healed by secondary intention or were complicated by infection: that is, wounds that were adversely affected by prolonged inflammation. Simple reexcision and closure is unlikely to improve a

FIGURE 4.12. Hypertrophic scars. These lesions are characteristic of acne scars that occur on the trunk. (Reproduced with permission from Goodheart HP. *Goodheart's Photoguide of Common Skin Disorders*, 2nd ed. Philadelphia, PA: Lippincott Williams & Wilkins; 2003.)

scar that was closed with proper alignment and that healed primarily without complications.²⁷

Unightly Scars

A wound that is closed under tension or without adequate or accurate alignment, or a wound that runs across the lines of natural skin tension, is often unsightly. Surgical excision and closure with attention directed to correcting the underlying cause of the unsightly scar usually results in improvement. When reexcising either a hypertrophic scar or an unsightly scar from other causes, reclosure with attention to relieving mechanical tension by the use of semipermanent or permanent intradermal sutures and everting wound closure, followed by treatment with taping and/or silicone gel sheeting, and judicious use of injected intralesional steroids can result in substantial improvement in the quality of the scar in a high percentage of cases.

FETAL WOUND HEALING AND STEM CELLS: THE POTENTIAL FOR TISSUE REGENERATION

The ultimate and as yet unrealized goal of wound healing research is achieving tissue regeneration as opposed to scar formation. Much interest and research have focused on the process of fetal wound healing and the role of stem cells in tissue repair, as both hold significant potential for the directed manipulation of the healing wound to attain true tissue regeneration.

It has been demonstrated that humans and several other mammalian species undergo fetal skin healing with little or no scar if the injury occurs early enough during gestation.^{28,29} The physiologic mechanisms involved in scarless fetal healing have been under active investigation. Adult wounds heal with a significant inflammatory response followed by abundant collagen deposition and remodeling into a mature scar. Numerous studies have shown that fetal wounds heal with little or no inflammation and no excess collagen formation. The fetal wound matrix is also higher in hyaluronic acid than the adult wound. This substance is seen only early in adult healing. Amniotic fluid is rich in hyaluronic acid and may provide the hyaluronic acid found in the fetal wound. Experiments that have exposed adult skin to amniotic fluid, however, demonstrate adult-type healing with scar formation. One important factor is that after the second trimester, fetal wounds begin to heal with scar, suggesting that the increased cell differentiation that occurs with maturation of the fetus is a critical factor in the scarless versus scarring phenotype.

Clearly, the fetal wound differs from the adult wound in several ways. The scarless healing appears multifactorial. Further research may identify factors (i.e., growth factors) that can be applied to wounds to diminish scar formation. This has potentially important application in virtually all of surgery but has proved to be elusive despite aggressive research interest.

Another promising and complementary approach for tissue regeneration has arisen from the realization that bone marrow-derived progenitor cells participate in the process of tissue repair. It is now appreciated that tissue hypoxia in a wound upregulates HIF-1, which in turn causes release of growth factors including VEGF and SDF-1. In addition to their well-recognized roles in angiogenesis and lymphocyte migration, respectively, both also serve to recruit marrow-derived progenitor cells such as endothelial progenitor cells and mesenchymal stem cells to the site of injury. The identification of other signals that mobilize and recruit stem cells to wounds is an area of active inquiry, as are the morphogenic pathways and cues that direct stem cells to develop into different tissue lineages. The

role that such cells play in tissue repair is currently being elucidated, and the potential of these cells to augment healing in disease states such as diabetes, as well as in clinical states associated with impaired healing such as advanced age, holds tremendous promise for all fields of surgery.³⁰

Tissue-derived stem cells also play a role in healing. It is likely that epithelial stem cells and dermis-resident cells have previously unappreciated functions in wound repair. The potential of other tissue-derived stem cells, such as adipose tissue-derived stem cells, in tissue repair is currently an area of intense research. The directed manipulation of stem and progenitor cells will likely define future advances in regenerative medicine, which is a direct offshoot of wound healing science.

CHAPTER 5 ■ HEMOSTASIS

PETER K. HENKE AND THOMAS W. WAKEFIELD

KEY POINTS

- 1 At the same time that thrombin forms, natural anticoagulant mechanisms oppose further thrombin formation and help to localize thrombin activity to areas of vascular injury. Just as thrombin generation is key to coagulation, antithrombin is the central anticoagulant protein.
- 2 The endothelial cell acts as a nonthrombogenic surface, and inflammation tips the balance to the procoagulant state.
- 3 Thrombosis and inflammation are closely linked, and may perpetuate each other. Leukocytes and chemokines are involved with normal deep venous thrombosis resolution.
- 4 Heparin agents are the primary anticoagulants for acute venous and arterial thrombosis, while a vitamin K antagonist is standard for long-term anticoagulation.
- 5 Factor VIII and IX deficiency states are involved in hemophilia A and B and von Willebrand disease.
- 6 Heparin-induced thrombocytopenia (HIT) occurs in 0.6% to 30% of patients in whom heparin is given; severe thrombocytopenia associated with thrombosis (HITS) is much less frequent. Cessation of heparin is critical.

BASIC CONSIDERATIONS

Coagulation is an essential homeostatic mechanism for survival and involves tightly controlled processes to maintain vascular integrity including thrombosis localization, amplification, and neutralization. These coordinated steps occur at the vessel, cellular, and subcellular level. Understanding of pathologic thrombosis and its basic hemostatic processes is essential for surgeons. Thrombosis, directly or indirectly, is the underlying leading cause of death in the world.

Platelets form the initial hemostatic plug and are locally activated and aggregation induced (Fig. 5.1). Platelet aggregation is mediated by receptors that are part of the mammalian integrin family. This family includes the β_1 family, mediating platelet interaction with cells, collagen, fibronectin, and laminin; the β_2 family (LeuCAM), present on leukocytes mediating interactions between leukocytes and other cells important in inflammation; and the β_3 family (cytoadhesion), including the megakaryocyte-specific glycoprotein (Gp) IIb/IIIa receptor and the vitronectin receptor present on platelets and other cells.¹ Platelet aggregation is mediated by GpIIb/IIIa, which binds fibrinogen, von Willebrand factor (vWF), fibronectin, vitronectin, and thrombospondin to activated platelets. These high-density receptors are hidden on inactivated platelets and become exposed on the surface of activated platelets.

Once stimulated, activated platelets contract, with externalization of negatively charged procoagulant phospholipids, including phosphatidylserine and phosphatidylinositol (termed *platelet factor 3*).² This allows for the coagulation proteins to assemble on the surfaces of platelets, accelerating the coagulation reaction.^{3,4} Platelet membranes contribute critical surfaces for coagulation complex assembly. During platelet activation, granules release their contents of calcium, serotonin, adenosine diphosphate (ADP), and adenosine triphosphate³ and membranes are exposed that are rich in receptors for factors Va and VIIa,^{5,6} as well as fibrinogen, vWF, and ADP, a potent activator of other platelets. vWF is responsible for platelet adhesion through binding to GpIb,⁷ whereas fibrinogen forms bridges between activated platelets by binding to GpIIb/IIIa on adjacent stimulated platelets.⁸ The GpIIb/IIIa receptor contains a binding site for the tripeptide sequence arginine-glycine-aspartic acid (RGD), which is common to many of the receptor proteins. Unstimulated platelets can also attach to immobilized

fibrinogen by the same receptor.⁹ Platelet activation leads to the release of arachidonic acid metabolites such as thromboxane A₂, a powerful initiator of platelet aggregation.¹⁰ Platelets also release microparticles (MPs), rich in tissue factor (TF) and other procoagulant products, that further accelerate the coagulation process.

Once the platelet plug has formed, the stage is set for coagulation protein assembly (Fig. 5.2). Initiating agents for coagulation include subendothelial collagen and TF, usually from vascular injury.¹¹ There is also growing evidence that blood-borne TF associated with leukocytes, or circulating in soluble form, is also involved with venous thrombogenesis.¹² Leukocyte adhesion to platelets may trigger leukocyte activation, causing recruitment of blood-borne TF onto the surface of leukocytes associated with thrombus or recruitment of TF-positive leukocytes onto the growing thrombus.¹³ TF, both blood-borne and local, activates the extrinsic pathway of coagulation by complexing with activated factor VII (VIIa) and activating factors IX and X to factors IXa and Xa.¹² The enzyme responsible for the initial activation of factor VII is unknown. However, factors Xa and VIIa amplify activation of factor VII. Activated factor X, activated factor V (Va), ionized calcium, and factor II (prothrombin) form on the platelet phospholipid surface to initiate the prothrombinase complex, which catalyzes the formation of thrombin faster than can be achieved with factor Xa alone³ (Fig. 5.3). When the amount of TF is limited, activation of factor IX rather than factor X is favored,¹⁴ allowing for coagulation in situations of low TF concentration.

Thrombin is central to coagulation and acts to cleave fibrinopeptide A (FPA) from the α chain of fibrinogen and fibrinopeptide B (FPB) from the β chain. This leads to the release of fibrinopeptides and the formation of new fibrin monomers, which then cross-link, resulting in fibrin polymerization. Thrombin also activates factor XIII, which catalyzes the cross-linking of fibrin to make the clot firm, activates platelets, and activates factors V and VIII, two nonenzymatic cofactors, to Va and VIIa.³ This is important because only activated factors Va and VIIIa are involved in coagulation. Factor XIIIa also cross-links other plasma proteins, such as fibronectin and α_2 -antitrypsin, resulting in their incorporation into clot.¹⁵

The intrinsic pathway of blood coagulation requires activation of factor XI to XIa. This may occur both by the contact activation system through activation of factor XII, plasma prekallikrein, and high-molecular-weight kininogen and, more

FIGURE 5.1. Primary hemostasis is achieved initially with a platelet aggregation as illustrated. Note that platelet adhesion, shape change, granule release followed by recruitment, and the hemostatic plug at the area of subendothelial collagen and collagen exposure are the initial events for thrombus formation.

important, through thrombin with negatively charged surfaces.¹⁶ Factor XIa activates factor XI autocatalytically and also catalyzes the conversion of factor IX to IXa. After activation, factor VIIIa dissociates from vWF and assembles with factors IXa and X. Factor IXa, factor X, ionized calcium, and thrombin-activated factor VIII (VIIIa) then assemble on the platelet surface in a complex called the *Xase complex* to catalyze the activation of factor X to Xa³ (Fig. 5.3). Factor Xa then shunts into the prothrombinase complex for further amplification of thrombin formation. The importance of a mechanism of factor XI activation independent of the contact activation system is apparent because patients deficient in those factors of the contact activation system, including factor XI, bleed, whereas patients deficient in factor XII, prekallikrein, and high-molecular-weight kininogen do not usually bleed.¹⁵ The contact activation system is the most important coagulation process involved in extracorporeal bypass circuits, including cardiopulmonary bypass and extracorporeal membrane oxygenation (ECMO).

NATURAL ANTICOAGULANT MECHANISMS

- At the same time that thrombin forms, natural anticoagulant mechanisms oppose further thrombin formation and help to

localize thrombin activity to areas of vascular injury. Just as thrombin generation is key to coagulation, antithrombin (AT) is the central anticoagulant protein (Fig. 5.4). This glycoprotein of 70-kD molecular weight binds to thrombin, preventing the removal of FPA and FPB from fibrinogen; prevents the activation of factors V and VIII; and inhibits the activation and aggregation of platelets. In addition, AT directly inhibits factors IXa, Xa, and XIa.

A second natural anticoagulant is activated protein C (APC), which inactivates factors Va^{17,18} and VIIIa, thus reducing the Xase and prothrombinase complex acceleration of the rate of thrombin formation. In the circulation, protein C is activated on endothelial cell surfaces by thrombin complexed with one of its receptors, thrombomodulin.^{19–21} The formation of this thrombin–thrombomodulin (TM) complex accelerates the activation of protein C compared with thrombin alone. Thrombin, at the same time, by binding to TM, loses its platelet-activating activity²² as well as its enzymatic activity for fibrinogen and factor V.²³ Protein S is a cofactor for APC.

Another innate anticoagulant is tissue factor pathway inhibitor (TFPI). This factor is bound to low-density lipoprotein (LDL) in plasma, and is also called lipoprotein-associated coagulation inhibitor. The protein binds to the TF–VIIa complex, inhibiting the activation of factor X to Xa and the formation of the prothrombinase complex.^{15,24} A fourth natural anticoagulant is heparin cofactor II.²⁵ Its

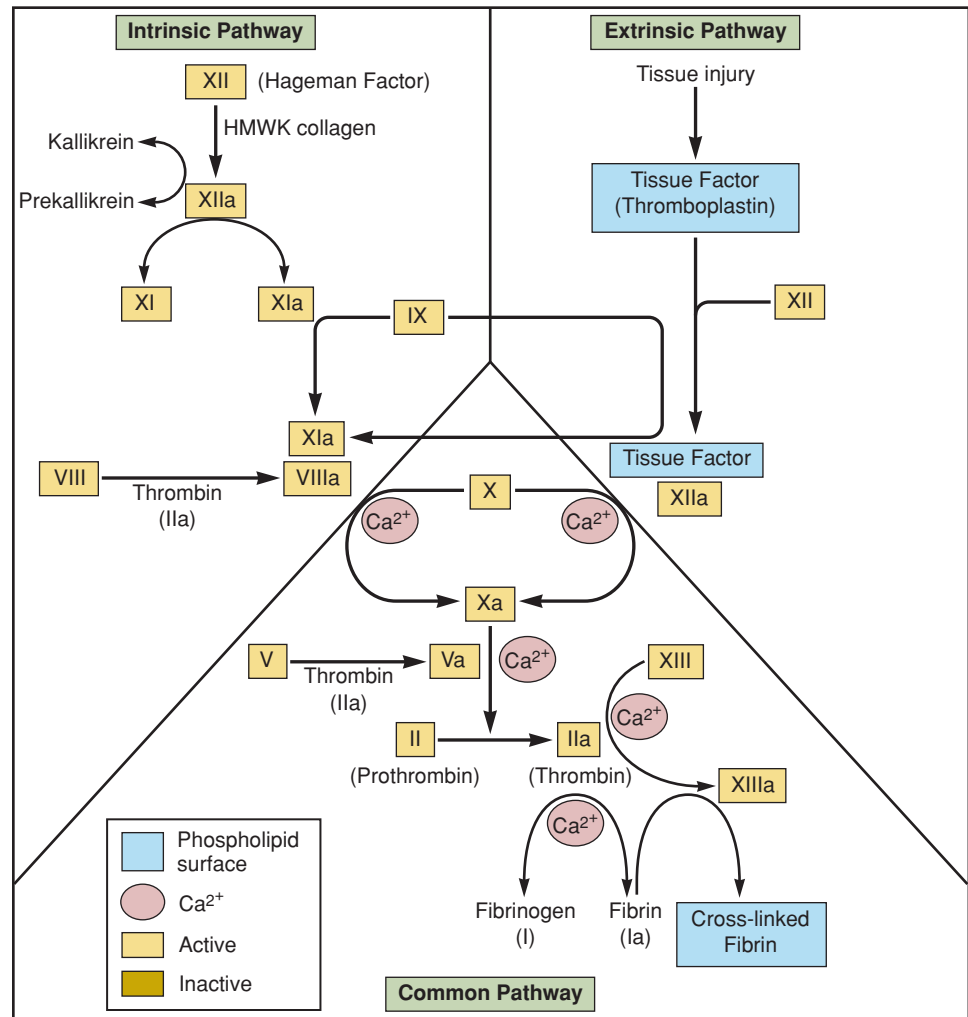

FIGURE 5.2. On the platelet surface, the clotting cascade involves both the intrinsic and extrinsic pathways. Tissue factor mRNA is transcribed and translated to active tissue factor, which activates factor VII to VIIa as a primary event.

FIGURE 5.3. The classical pathway showing the interface between the intrinsic pathway, extrinsic pathway, and common pathway is illustrated with the ultimate production of thrombin. This catalyzes fibrin from fibrinogen and then cross-links the fibrin to form a stable clot.

concentration in plasma is estimated to be significantly less than that of AT, and its action is implicated primarily in the regulation of thrombin formation in extravascular tissues. Finally, thrombin is inactivated when it becomes incorporated into the clot.

FIBRINOLYSIS

In addition to natural anticoagulants such as protein C and S, physiologic clot formation is balanced by a contained process of clot lysis, which prevents thrombus formation from proceeding outside of the injured area (Fig. 5.5). The central fibrinolytic enzyme is plasmin, a serine protease generated by the proteolytic cleavage of the proenzyme plasminogen. Its main substrates include fibrin, fibrinogen, and other coagulation factors. Plasminogen, tissue plasminogen activator (tPA), and α_2 -antiplasmin (α_2 -AP) become incorporated into the fibrin clot as it forms.³ Plasminogen activators are serine proteases that activate plasminogen, by cleavage of a single arginine-valine peptide bond, to the enzyme plasmin. Plasminogen activation provides localized proteolytic activity.^{26–28} In fact, thrombin promotes tPA release from endothelial cells as well as the production of plasminogen activator inhibitor-1 (PAI-1) from endothelial cells.^{29,30}

The major categories of plasminogen activators include exogenous factors, such as streptokinase; endogenous factors, such as tPA and urokinase; and intrinsic factors, such as factor XII, prekallikrein, and high-molecular-weight kininogen.³ These later factors of the contact system are more important in

clot lysis than thrombus formation. These enzymes may also liberate bradykinin from high-molecular-weight kininogen, resulting in an increase in vascular permeability, prostacyclin liberation, and tPA secretion. Finally, APC has been found to proteolytically inactivate the inhibitor to tPA, thus promoting tPA activity and fibrinolysis.³¹

Fibrin, when digested by plasmin, yields one molecule of fragment E and two molecules of fragment D. In physiologic clot formation, fragment D is released in dimeric form (D-dimer)^{3,15} and is a marker for fibrinolysis of formed clot. An elevated D-dimer level after treatment of deep venous thrombosis (DVT) is one biomarker that has been found to accurately predict an ongoing risk of recurrent venous thromboembolisms (VTE).³²

Two primary inhibitors of plasmin are important. First, α_2 -AP is released by endothelial cells and complexes with plasmin. In physiologic fibrinolysis, α_2 -AP is bound to fibrin and excess plasmin is readily inactivated. In plasma, PAI-1 is the primary inhibitor of plasminogen activators. It is secreted in an active form from liver and endothelial cells and stabilized by binding to vitronectin (Vn). PAI-1 levels are elevated by hyperlipidemia, and PAI-1 elevation appears to synergize with factor V Leiden genetic abnormalities.³³

In summary, coagulation is an ongoing process of thrombus formation, inhibition of thrombus formation, and thrombus dissolution. The central mediators are TF, platelets, thrombin, and plasmin. Abnormalities in coagulation occur when one process—thrombus formation, thrombus inhibition, or fibrinolysis—overcomes the others and dominates the delicate balance.

FIGURE 5.6. The endothelium is a primary interface allowing anticoagulant functions in the resting state, with prostacyclin, nitric oxide, plasminogen activators, and thrombomodulin. Procoagulant proteins are expressed on activated endothelium including selectins; procoagulant proteins, such as the von Willebrand factor; tissue factor; and plasminogen activator inhibitor-1.

ENDOTHELIUM AND HEMOSTASIS

Through its ability to express procoagulants and anticoagulant factors, vasoconstrictors and vasodilators, and key cell adhesion molecules and cytokines, the endothelial cell is a key regulator of hemostasis³⁴ (Fig. 5.6). Vascular endothelium maintains a vasodilatory and local fibrinolytic state in which coagulation, platelet adhesion and activation, and leukocyte activation are suppressed.

2 Endothelial products that are vasodilatory include adenosine, nitric oxide (NO), and prostacyclin (PGI₂).³⁵ A non-thrombogenic endothelial surface is maintained by four main mechanisms including endothelial production of thrombomodulin and subsequent activation of protein C, endothelial expression of surface heparan- and dermatan-sulfate, constitutive expression of TFPI by endothelium (which is markedly accelerated in response to heparin), and local production of tPA and urokinase plasminogen activator (uPA).^{34,36} Finally, the elaboration of NO and interleukin (IL)-10 by endothelium inhibits leukocyte adhesion and activation.³⁵

During states of endothelial disturbances such as injury, a prothrombotic and proinflammatory state of vasoconstriction is supported by the endothelial surface. Endothelial release of platelet-activating factor (PAF) and endothelin-1 promotes vasoconstriction.³⁶ Endothelial cells increase production of vWF, TF, PAI-1, and factor V to augment thrombosis with exposure to prothrombotic stimuli. Finally, in response to endothelial injury, endothelial cells are activated, resulting in increased surface expression of cell adhesion molecules (such as P- or E-selectin), and promotes leukocyte adhesion and activation. This initiates and amplifies inflammation and thrombosis.

THROMBOSIS, INFLAMMATION, AND RESOLUTION

After venous thrombosis, an acute to chronic inflammatory response occurs in the vein wall and thrombus, leading to thrombus amplification and organization and vein recanalization (often at the expense of vein wall and vein valvular damage). Initially, there is an increase in neutrophils in the vein wall followed by monocytes/macrophages. Cytokines, chemokines, and inflammatory factors (e.g., tumor necrosis factor [TNF]) facilitate inflammation. The ultimate response of the vein wall depends on proinflammatory and anti-inflammatory mediator balance at the interface between the leukocyte, activated platelet, and endothelium.³⁷

Selectins (P- and E-selectin) have been found to be intimately involved in this process³⁸ (Fig. 5.7). Selectins are the first upregulated glycoproteins on activated platelets and endothelial cells. The P-selectin receptor is P-selectin glycoprotein ligand-1 (PSGL-1). This receptor, expressed on leukocytes, facilitates the initial rolling of inflammatory cells along stimulated vascular endothelium. Interactions between P-selectin and PSGL-1 mediate leukocyte-endothelial cell and leukocyte-platelet interactions.

PSGL-1 has the greatest affinity for P-selectin and lesser affinity for E-selectin and L-selectin. The role of P-selectin in venous thrombosis has been suggested by the study of a mouse with high circulating levels of P-selectin, the Delta CT mouse.³⁹ This mouse has a normal phenotype but expresses circulating plasma P-selectin threefold to fourfold higher than wild-type mice. These mice are hypercoagulable based on clotting tests, and a receptor antagonist against the P-selectin receptor (rPSGL-Ig) will reverse the hypercoagulability. Consistently, wild-type mice administered soluble P-selectin become

FIGURE 5.7. The interaction between stasis injury and procoagulant syndromes are represented by Virchow's triad. Endothelial and vascular injury causes leukocytes and platelets to express P- and E-selectin and the P-selectin glycoprotein ligand-1 (PSGL-1) receptor. Microparticles are released, which express tissue factor. This stimulates the coagulation pathway, fibrin production, and thrombus amplification.

hypercoagulable. In models of venous thrombosis, P-selectin inhibition given prophylactically decreases thrombosis in a dose-dependent fashion and can treat established venous thrombosis as effectively as heparin without anticoagulation.^{40,41}

Microparticles (<1 micron fragments) may be central for P-selectin's effect. It is believed that with initial thrombosis, selectin upregulation leads to MP formation. These procoagulant MPs, which may express TF, are then recruited into the area of developing thrombosis, amplifying the process. Consistently, P-selectin and E-selectin gene deficiency results in less MP formation and less thrombosis.⁴² In a mouse model of inferior vena cava (IVC) thrombosis, the Delta CT mouse has increased thrombosis, associated with elevated levels of MPs.⁴² In a similar experimental study, the generation of procoagulant activity was shown to be dependent on P-selectin: PSGL-1 interactions related to MP formation.⁴³ The procoagulant nature of these MPs was demonstrated by their ability to normalize bleeding in factor VIII-deficient mice.

3 Inflammatory cells are important to the process of thrombus recanalization and organization³⁸ (Fig. 5.8). Thrombus DVT resolution resembles wound healing and involves profibrotic growth factors, collagen deposition, and matrix metalloproteinase (MMP) expression and activation. The fact that leukocytes invade the thrombus in a specific sequence suggests their importance in the normal thrombus resolution.⁴⁴

The first cell type in the thrombus is the neutrophil (polymorphonuclear leukocytes [PMNs]). Although PMNs may cause vein wall injury, they are essential for early thrombus resolution by promoting both fibrinolysis and collagenolysis.^{45,46} In a rat model of stasis DVT, neutropenia was associated with larger thrombi at 2 and 7 days and was correlated with increased thrombus fibrosis and significantly lower thrombus levels of both uPA and MMP-9.⁴⁷ Neutropenic cancer patients are not protected from DVT, and multiple neutropenic episodes are associated with recurrent VTE in patients with malignant disease who required filter placement due to a failure of, or contraindication to, anticoagulation.⁴⁸

The monocyte is likely the most important cell for later DVT resolution. Monocyte influx into the thrombus peaks at day 8 after thrombogenesis and correlates with elevated monocyte chemotactic protein-1 (MCP-1) levels,⁴⁹ which has been associated with DVT resolution.⁵⁰ Targeted deletion of the CC receptor-2 (CCR-2 KO) in the mouse model of stasis thrombosis was associated with late impairment of thrombus resolution, probably via impaired MMP-2 and MMP-9 activity. We also found that CCR-2 KO mice with stasis thrombosis supplemented with exogenous interferon- γ had full restoration of thrombus resolution, in part due to recovery of MMP-2 and MMP-9 activities, and without an increase in thrombus monocyte influx.⁵¹

FIGURE 5.8. The proposed resolution mechanism involves both early thrombolysis with a large distending clot and then, over time, a fibrotic thrombus that resembles scar tissue as produced. Note that proinflammatory factors, as well as neutrophils and matrix metalloproteinases, are present early with subsequent vein wall injury related to collagenolysis and elastinolysis. Later, vascular smooth muscle cell proliferation appears to occur, with thrombus resolution and an increase in profibrotic growth factors such as interleukin-13 and transforming growth factor- β . This promotes collagen accumulation.

Thrombi have been found to contain increasing amounts of both tPA and uPA activity as they resolve, and this activity is expressed by invading monocytes.^{52,53} In a recent study, mice genetically deleted for uPA had impaired thrombus resolution with reduced cell infiltration restricted primarily to the margins of the thrombus, with few neovascular channels present.⁵⁴ Mice genetically deleted for tPA, however, were not similarly affected, suggesting that uPA, not tPA, is responsible for this activity. Absence of uPA was also associated with delayed monocyte recruitment into the thrombus.

As the thrombus resolves, a number of proinflammatory factors are released into the local environment, including IL-1 β and tumor necrosis factor- α (TNF- α).⁴⁴ The cellular sources of these different mediators have not been specifically defined but likely include leukocytes and smooth muscle like cells within the resolving thrombus. Based on our model of stasis DVT in the rat, elastinolysis seems to occur early, as measured by an increase in vein wall stiffness; persists through 14 days; and is accompanied by elevated MMP-2 and MMP-9 activities. However, early vein wall collagenolysis rather than deposition seems to occur within the first 7 days, representing an acute response to injury.⁵⁵

Taken together, inflammation is important for thrombus organization and recanalization, with neutrophils setting the early stage for later monocyte activity.

ARTERIAL VERSUS VENOUS THROMBOSIS

Thrombosis in the arterial system occurs somewhat differently than in the venous system (Fig. 5.9). The elements required for the initiation of venous thrombosis were described by Virchow as stasis, endothelial injury, and hypercoagulability of the blood. In the arterial circulation, endothelial injury (whether acute or chronic) is key to thrombosis. This is most clearly demonstrated by the typical atherosclerotic plaque. In advanced lesions, the lipid core of the plaque is rich in inflammatory cells, cholesterol crystals, and TF (generated by activated macrophages within the plaque).⁵⁶ Plaque ulceration exposes highly thrombogenic lipid to the bloodstream, activating coagulation and platelet aggregation and leading to the deposition of clot.⁵⁷ Platelet deposition occurs at the apex of stenosis, the point of maximal shear force.

A platelet-rich thrombus is observed in arterial thrombus, while in contrast, venous blood stasis and changes in its composition (leading to hypercoagulability) incite the formation of thrombus from local procoagulant events, including small endothelial disruptions at venous confluences, saccules, and valve pockets. Hypercoagulable states have classically been highly associated with VTE, but do play a role in cardiovascular disease as well. For example, both factor V Leiden and

FIGURE 5.9. A: Depicted here is the typical atherosclerotic thrombotic nidus, which includes rupture of a plaque, composed of smooth muscle, foam cells, and leukocytes. Platelets are the primary intermediary in arterial thrombosis, as well as tissue factor. B: Increased coagulability, as well as vessel wall changes with procoagulant tissue factor expression, promotes thrombosis.

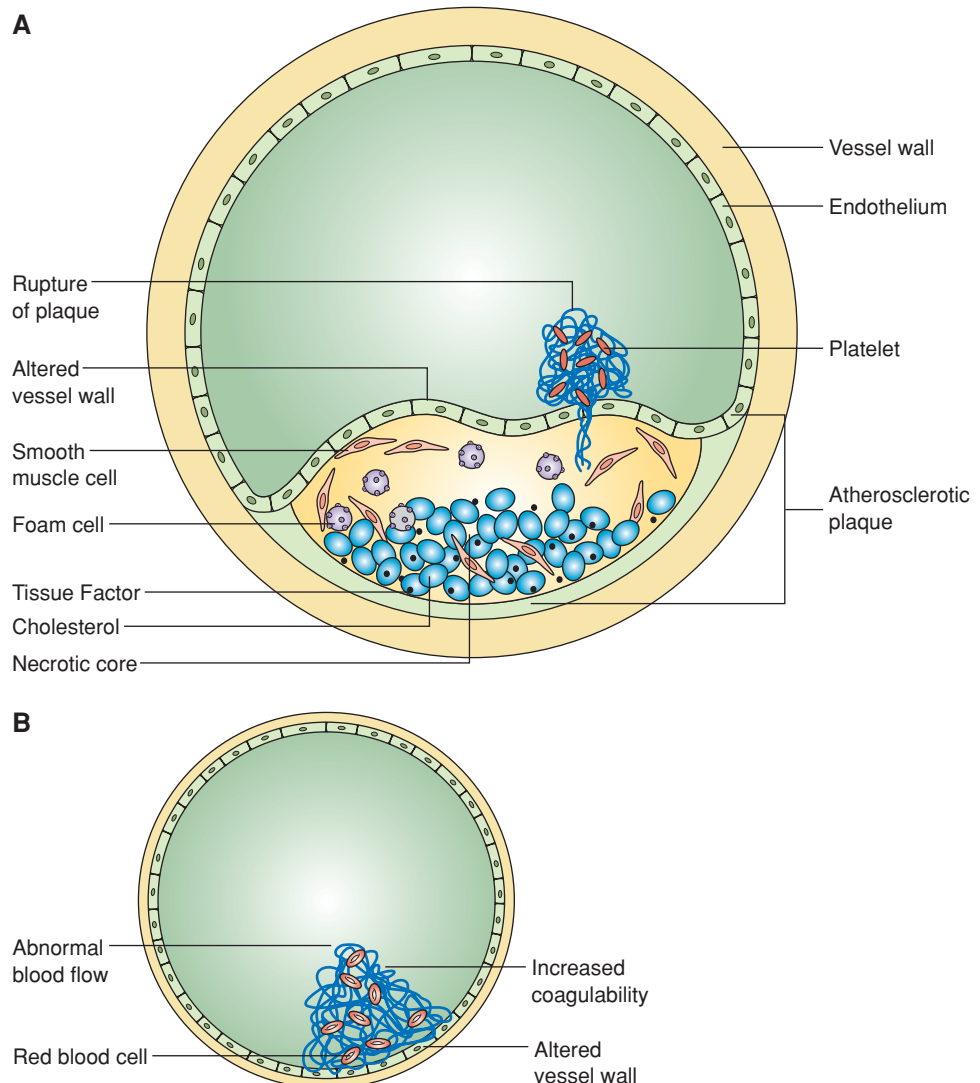

TABLE 5.1

FREQUENCY OF THROMBOSIS DUE TO HYPERCOAGULABLE STATES

■ HYPERCOAGULABLE STATE	■ FREQUENCY (%)
Factor V Leiden	20–60
Hyperhomocysteinemia	10
PT G20210A	4–6
Protein C deficiency	3–5
Protein S deficiency	2–3
Dysfibrinogenemia	1–3
Antithrombin	1–2
Dysplasminogenemia	<1

PT, prothrombin.

prothrombin 20210 A mutation are associated with coronary artery disease and stroke.⁵⁸

PROCOAGULANT STATES

Refer to Tables 5.1 to 5.3 and Algorithm 5.1.

ACQUIRED PROCOAGULANT STATES

Most thrombotic clinical episodes have a proximate cause, although environmental risks and genetic predispositions to thrombosis may account for many of the VTE that manifest clinically. Risk factors for arterial thrombosis are primarily related to atherosclerosis, and are detailed elsewhere.

The most common risk factors for venous thrombosis are prior DVT, malignancy, immobility, intravenous catheters, increased age, major surgery, trauma, infections such as pneumonia and urinary tract infection, and certain cytotoxic chemotherapy regimens.^{59–61} Certain medications such as oral contraceptives and hormonal replacement therapies also increase the risk of VTE.

Of primary importance to surgeons is how to best estimate perioperative VTE risk and apply appropriate prophylaxis.

TABLE 5.2

SEVERITY OF VTE DUE TO HYPERCOAGULABLE STATES

High risk for thrombosis
■ AT deficiency
■ Protein C deficiency
■ Protein S deficiency
■ HIT/HITTS
■ Antiphospholipid antibody syndrome
Lower risk for thrombosis
■ Factor V Leiden
■ Hyperhomocysteinemia
■ PT G20210A
■ Dysfibrinogenemia
■ Dysplasminogenemia
■ Elevated factors VIII, IX, and XI

AT, antithrombin; HIT, heparin-induced thrombocytopenia; HITTS, heparin-induced thrombocytopenia and thrombosis syndrome; PT, prothrombin; VTE, venous thromboembolism.

TABLE 5.3

ANATOMIC LOCATION OF VTE DUE TO HYPERCOAGULABLE STATES

Arterial

- Elevated fibrinogen
- Abnormal platelet aggregation
- Atherosclerosis
- Lipoprotein(a)

Both arterial and venous

- Hyperhomocysteinemia
- HITTS
- Antiphospholipid antibody
- Elevated PAI-1

Venous

- AT
- Protein C
- Protein S
- Factor V Leiden
- PT G20210A
- Dysfibrinogenemia
- Elevated factors XI, IX, and VIII

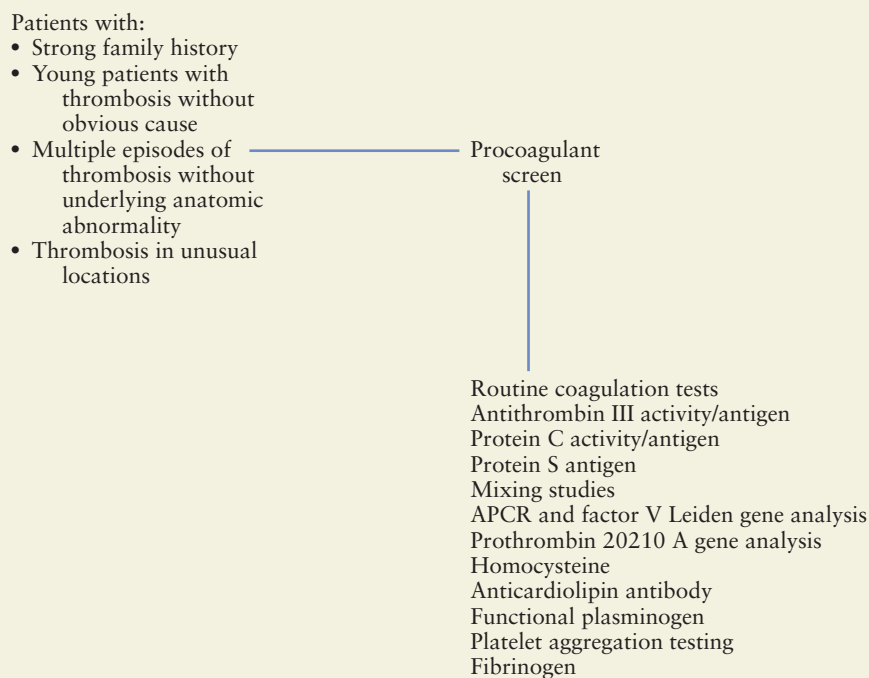

AT, antithrombin; HITTS, heparin-induced thrombocytopenia and thrombosis syndrome; PAI-1, plasminogen activator inhibitor; PT, prothrombin; VTE, venous thromboembolism.

This can be done with a screening form, such as that devised by Caprini⁶² (Fig. 5.10). Essentially, this is a focused assessment of VTE risks related to current illnesses and history that may not be fully covered in the routine history and physical examination. The recommendations are also well detailed in the routinely updated American College of Chest Physicians VTE evidence-based guidelines.⁶³ The higher the risk, the more intensive the prophylaxis is. For example, an outpatient hernia patient may require no prophylaxis outside of early ambulation, whereas an obese patient having a hip replacement would be best treated with anticoagulation as well as sequential compression devices for the lower extremities. However, all patients should be assessed for VTE risk. This is a quality and safety measure by U.S. governing bodies such as the Joint Commission and Centers for Medicare and Medicaid Services.

Lupus Anticoagulant/Antiphospholipid Syndrome (Antiphospholipid Antibody)

This condition, despite its name, is a prothrombotic state and deserves expanded discussion. The antiphospholipid antibody syndrome consists of an elevated antiphospholipid antibody titer in association with thrombosis, recurrent fetal loss, thrombocytopenia, and livedo reticularis.^{64,65} Strokes, myocardial infarction, visceral infarction, and extremity gangrene may also occur. Although the lupus anticoagulant has been noted often in patients with systemic lupus erythematosus (SLE), it does occur in patients without SLE. It may also be induced in patients by medications, cancer, and certain infections.⁶⁶

This syndrome is associated with antiphospholipid antibodies that are most commonly immunoglobulin G (IgG). Antiphospholipid antibody syndrome is a particularly virulent hypercoagulable state that results in arterial and venous thrombosis at 5- to 16-fold greater risk.^{66–68} A number of possible thrombotic mechanisms have been suggested, including inhibition of prostacyclin synthesis or release from endothelial cells,⁶⁹ inhibition of APC by thrombin/TM,⁷⁰ elevated PAI-1 levels,⁶⁷ platelet activation,⁷¹ endothelial cell activation,⁷² and interference with the endothelial cell-associated annexin V anticoagulant activity.⁷³ Increased

**ALGORITHM 5.1****ALGORITHM 5.1.** Coagulation analysis.

TF expression on monocytes and low free protein S plasma levels have also been found with the antiphospholipid syndrome and a history of thrombosis.⁷⁴

At least one third of patients with lupus anticoagulants have a history of one or more thrombotic events, 70% or more being VTE.⁷⁵ Graft thrombosis has been observed in 27% to 50% of patients positive for antiphospholipid antibody.^{76,77}

The diagnosis should be suspected in someone with a prolonged activated partial thromboplastin time (aPTT) with other standard coagulation tests normal, along with the presence of an increased antiphospholipid or anticardiolipin antibody titer and elevation of α_2 -glycoprotein I.^{3,78} The prolongation in the aPTT is strictly a laboratory phenomenon. The dilute Russell viper venom time confirms the presence of a lupus anticoagulant.

There is imperfect agreement between diagnostic tests for this abnormality. Approximately 80% of patients with a prolonged aPTT will have a positive antiphospholipid antibody, but only 10% to 50% of patients with a positive antiphospholipid antibody will have a prolonged aPTT.⁷⁹ Patients with both tests positive are reported to have the same thrombotic risk as those with either test alone.

Heparin followed by warfarin has been recommended for the treatment of the antiphospholipid syndrome.^{66,75} For recurrent fetal loss, heparin or low-molecular-weight heparin (LMWH) use through pregnancy is recommended. In patients with lupus anticoagulants, heparin is monitored by antifactor Xa levels.

XIIa, and XIa. It is synthesized in the liver and has a half-life of 2.8 days. AT deficiency accounts for approximately 1% to 2% of episodes of VTE and may occur at unusual sites such as mesenteric or cerebral veins. Arterial and graft thrombosis have also been described in AT deficiency.^{80,81} Most cases become apparent by 50 years of age.⁸² Homozygous patients usually die in utero, whereas heterozygous patients usually demonstrate AT levels less than 70% of normal. Acquired AT deficiency results from liver disease, malignancy, sepsis, disseminated intravascular coagulation (DIC), malnutrition, and renal disease.⁸⁰

The diagnosis of AT deficiency is suspected in a patient who cannot be adequately anticoagulated with heparin or who develops thrombosis while on heparin and is made by measuring AT antigen and activity levels. However, patients should not have been exposed to heparin or related compounds for at least 2 weeks to have accurate values. Heparin decreases AT levels 30%, and this effect can occur up to 10 days after stopping intravenous heparin therapy.⁷⁸ Conversely, warfarin increases AT levels.

For a patient with AT deficiency, anticoagulation with heparin requires the administration of fresh frozen plasma to provide AT, 2 units every 8 hours, decreasing to 1 unit every 12 hours, followed by oral anticoagulation. A reasonable alternative includes anticoagulation with direct thrombin inhibitors such as lepirudin, argatroban, or bivalirudin.⁶³ Aggressive prophylaxis against VTE is recommended during the perioperative period, and usually lifelong anticoagulation therapy is required after a first episode of significant VTE.^{63,83}

INHERITED PROCOAGULANT STATES

Defects with High Risk for Thrombosis

Antithrombin Deficiency. AT is a serine protease inhibitor (SERPIN) of thrombin, kallikrein, and factors Xa, IXa, VIIa,

Protein C and S Deficiencies. Protein C and its cofactor protein S are both vitamin K–dependent factors synthesized in the liver with half-lives of 4 to 6 hours and 12 to 14 hours, respectively. The majority of cases of protein C or protein S deficiency are inherited as autosomal dominant. Patients present with VTE, often between the ages of 15 and 30 years.^{83,84} Protein C and S deficiency states are responsible for approximately

2% to 5% of patients with VTE. However, cases of arterial thrombosis have also been reported.⁸⁵ If present as a homozygous state at birth, infants usually die from unrestricted clotting and fibrinolysis, a condition of extreme DIC termed *purpura fulminans*. Patients heterozygous for protein C deficiency usually have antigenic protein C levels less than 60% of normal.^{78,86} Acquired protein C deficiency occurs with liver failure, DIC, and nephrotic syndrome.

Protein S is a cofactor to protein C and is regulated by complement C4b-binding protein. Free protein S is functionally active as an anticoagulant. The deficiency of protein S results in a clinical state identical to protein C deficiency. Nephrotic syndrome can lead to a reduction in free protein S,⁸⁷ whereas inflammatory states such as SLE can result in an elevation of C4b-binding protein, reducing free protein S.

The diagnosis of protein C or S deficiency is made by measuring plasma protein C and S levels.^{3,88} For protein C, both antigen and activity are measured, whereas for protein S, only antigen is measured. A condition also exists in which there is an abnormality in the function of protein C itself, resulting in a decrease in protein C activity without a decline in antigenic protein C.⁸⁴

Treatment consists of anticoagulation, initially with heparin, usually followed by lifelong oral anticoagulation after a first thrombotic event. However, not all patients with low levels develop VTE. Many heterozygous family members of homozygous protein C-deficient infants also are unaffected.³¹ Thus, the institution of anticoagulation therapy in patients should occur only following an episode of thrombosis. However, aggressive anticoagulant prophylaxis during perioperative periods or high-risk environmental situations is necessary for asymptomatic heterozygote carriers.

With the initiation of oral anticoagulation, blood may become transiently hypercoagulable as the vitamin K-dependent factors with short half-lives are inhibited (factor VII, protein C) before the other vitamin K-dependent factors (factors II, IX, and X).⁸⁹ In someone already partially deficient in protein C or S, the levels of these anticoagulant factors will diminish even further with the initiation of warfarin. This results in temporary hypercoagulability, resulting in thrombosis in the microcirculation and warfarin-induced skin necrosis.⁹⁰ This leads to full-thickness skin loss, especially over fatty areas such as the breasts, buttocks, and abdomen. This complication can

VTE Risk and Suggested Prophylaxis For Surgical Patients

Total Risk Factor Score	Incidence of DVT	Risk Level	Prophylaxis Regimen	Legend
0-1	< 10%	Low Risk	No specific measures; early ambulation	IPC – Intermittent Pneumatic Compression LDUH – Low Dose Unfractionated Heparin LMWH – Low Molecular Weight Heparin FXa I – Factor Xa Inhibitor
2	10-20%	Moderate Risk	IPC, LDUH(5000 U BID) or LMWH (<3400 U)	
3-4	20-40%	High Risk	IPC, LDUH (5000 U TID), or LMWH (>3400 U) or FXa I	
5 or more	40-80% 1-5% mortality	Highest Risk	Pharmacological: LDUH, LMWH*, Warfarin* or FXa I* alone or in combination with IPC	

Prophylaxis Safety Considerations: Check box if answer is 'YES'

Anticoagulants: Factors Associated with Increased Bleeding

- ☐ Is patient experiencing any active bleeding?
 - ☐ Does patient have (or has had history of) heparin-induced thrombocytopenia?
 - ☐ Is patient's platelet count <100,000/mm³?
 - ☐ Is patient taking oral anticoagulants, platelet inhibitors (e.g., NSAIDS, Clopidogrel, Salicylates)?
 - ☐ Is patient's creatinine clearance abnormal? If yes, please indicate value _____
- If any of the above boxes are checked, the patient may not be a candidate for anticoagulant therapy and you should consider alternative prophylactic measures: IPC or Foot Pump.

Intermittent Pneumatic Compression (IPC)

- ☐ Does patient have severe peripheral arterial disease?
 - ☐ Does patient have congestive heart failure?
 - ☐ Does patient have an acute superficial/deep vein thrombosis?
- If any of the above boxes are checked, then patient may not be a candidate for intermittent compression therapy and you should consider alternative prophylactic measures. (IVC filter?)

be prevented by initiating warfarin therapy under the protection of systemic heparin anticoagulation or a direct thrombin inhibitor.

Defects with Lower Risk for Thrombosis

Resistance to Activated Protein C (Factor V Leiden).

Resistance to APC is reportedly present in 20% to 60% of cases of idiopathic VTE and is the most common underlying abnormality associated with VTE. This disorder is present in 1% to 2% of the general population.⁹¹⁻⁹³ It confers a relatively low risk for thrombosis, however, and is more common in whites than in nonwhite Americans.⁹¹ As a result of the substitution of a single amino acid, glutamine for arginine, at position 506 in the protein for factor V, caused by a nucleotide substitution of guanine for adenine at 1691 in the factor V gene, hypercoagulability is conferred by resistance to inactivation of factor Va by APC.⁹⁴⁻⁹⁶ Additionally, less VIIIa is interfered with, compounding the hypercoagulability.

Thrombotic manifestations are noted in those individuals both homozygous and heterozygous for this mutation. The relative risk for VTE in patients heterozygous for factor V Leiden is sevenfold, whereas the relative risk is 80-fold for those homozygous for factor V Leiden.⁹⁵ In contrast to factor defi-

ciency states, persons homozygous for this mutation usually do not die in infancy. Additionally, thrombosis is potentiated in the presence of additional acquired risk factors.^{95,97}

Combined defects with other hypercoagulable states, such as protein C and S deficiency or prothrombin G20210A, are not uncommon and increase the thrombotic risk.^{98,99} In addition to cases of VTE, recurrent VTE is also more common in patients with this entity, with a relative risk 2.4-fold.⁹³ Although VTE predominates in patients with this syndrome, arterial thrombosis has also been reported.¹⁰⁰

The diagnosis of APC resistance is made by a clot-based functional assay with the addition of APC (modified aPTT). Additionally, genetic analysis should be performed to confirm heterozygosity versus homozygosity, as treatment decisions may be different between the two states. If the patient has a known lupus anticoagulant syndrome, this entity may interfere with the clot-based APC resistance assay¹⁰¹ and genetic analysis is more accurate.

Treatment options for APC resistance after VTE include anticoagulation, initially heparin or LMWH, followed by oral anticoagulation. The long-term use of warfarin is controversial. No data exist to suggest that long-term warfarin should be given after a first episode of VTE in a patient heterozygous for the mutation.⁶³ The fact that APC resistance is a relatively low risk for recurrent thrombosis (2.4-fold) suggests that not

all patients after their first episode of VTE need long-term anticoagulant treatment. Patients must be evaluated in light of their overall risk for bleeding versus thrombosis.⁸³

Prothrombin G20210A Polymorphism. Prothrombin (factor II), a vitamin K-dependent factor synthesized in the liver, becomes thrombin when activated. A genetic polymorphism in the distal 3' untranslated region of the gene for prothrombin has been described in patients with VTE. This results in a normal prothrombin but at increased levels.^{84,97,102} This polymorphism confers an increased risk for VTE by two- to sevenfold, and is associated with 4% to 6% of patients with VTE.^{83,103,104} This thrombosis risk is increased in pregnant women,¹⁰⁵ in women with early myocardial infarctions,¹⁰⁶ and in synergy with factor V Leiden.⁹⁷ Most patients are heterozygous for this mutation, and whites are more often affected than those of Asian or African descent.¹⁰⁶ Genetic analysis is the marker for this abnormality.¹⁰⁷

Patients who present with VTE should be treated according to current standards and akin to the treatment for heterozygous factor V Leiden. Individuals with prothrombin G20210A who have recurrent episodes of VTE should undergo lifelong anticoagulation, as should those patients with both prothrombin G20210A and factor V Leiden.⁹⁷

Hyperhomocysteinemia. Hyperhomocysteinemia has been a known risk factor for atherosclerosis and vascular disease for more than 25 years, though a direct cause-and-effect relationship has not been established.^{108–110} However, a recent meta-analysis suggests the risk of VTE to be 2.5-fold with elevated homocysteine levels.¹¹¹ Two enzyme deficiencies, N⁵, N¹⁰, methylene tetrahydrofolate reductase (MTHFR) or cystathionine β -synthase, are responsible for elevated homocysteine levels.¹¹² Deficiencies in vitamins B₆ and B₁₂ and folate also contribute to elevations in homocysteine. Although mutations in these enzymes are not infrequent, the common polymorphism in MTHFR alone is not a factor in either the elevation of plasma homocysteine or thrombosis.¹¹³

Hyperhomocysteinemia also has been found to be a risk factor for VTE in those younger than 40 years,¹¹⁴ in women,¹⁰⁸ and for recurrent venous thrombosis in patients between 20 and 70 years of age.¹⁰⁹ The combination of hyperhomocysteinemia and factor V Leiden results in an increased risk of venous and arterial thromboses.¹¹⁵ Elevated plasma homocysteine results in abnormal endothelial function.^{116–120} Fasting homocysteine levels are determined from serum, usually on two occasions. The test may also be performed after a methionine oral loading regimen.^{121,122}

Homocysteine elevation is treated with folate supplements. Although the association between hyperhomocysteinemia and VTE has been established, treatment to lower homocysteine levels and the long-term effects of such treatment on procoagulant activity have yet to be validated.¹⁰⁸

Other Disorders Associated with Thrombosis

Defective Fibrinolysis/Dysfibrinogenemia/Lipoprotein(a). Abnormal plasminogens (dysplasminogenemias), although rare (<1%), have been described in cases of spontaneous arterial or VTE.¹²³ Other defects in fibrinolysis may affect up to 10% of the normal population.¹²⁴ Abnormal fibrinogens may account for 1% to 3% of patients with venous thrombosis and those presenting with digital ischemia.¹²⁵ Numerous molecular defects have been classified. Defective thrombin binding or resistance to plasmin-mediated breakdown has been described.¹²⁶ Although not clearly documented, defects in plasminogen activators, tPA, or uPA may incite thrombotic events.¹²⁷ Moreover, elevated PAI-1 has been associated with DVT and myocardial infarction.¹²³ Although the relationship between VTE and abnormal fibrinolysis is debated, it is clear that in the postoperative period there

is a connection between fibrinolysis and VTE.^{123,128,129} Additionally, PAI-1 is upregulated by thrombin, endotoxin, and IL-1, explaining the elevated circulating levels of PAI-1 during infections.¹³⁰ Lipoprotein(a), associated with LDL, has both atherogenic and prothrombotic properties.^{131–133} It prevents plasminogen from binding to cells or fibrin and inhibits fibrinolysis.¹³⁴ Elevated levels of lipoprotein(a) have been associated with VTE in childhood; it is a weak thrombotic risk factor in adults.¹³⁵

When an individual with thrombosis presents with one of the previously mentioned abnormalities, standard anticoagulation is necessary.^{136,137}

Abnormal Platelet Aggregation. It has been recognized for some time that there are patients who have thrombosis and may have hyperactive or hyperresponsive platelets, but this entity is poorly defined. Diabetes mellitus, which is known to be associated with hyperactive platelets and hyperlipidemic states, may be a contributing factor. Two clinical settings in which abnormal platelet aggregation has been associated with thrombosis include advanced malignancy of the lung and uterus and after carotid endarterectomy. Hyperactive platelets have also been noted during graft thrombosis in peripheral vascular reconstructions.⁶⁷ Although platelet aggregation assays may be helpful in making the diagnosis, these assays are not commonly performed or standardized and, thus, the incidence and importance of platelets to thrombosis are not well known. Bleeding time measurements are not specific and are not recommended for making this diagnosis.

Standard anticoagulant treatment is recommended for this condition. Aspirin and the thienopyridine derivatives such as clopidogrel may be useful, but their utility is unknown.¹³⁸

Elevated Procoagulant Factors: VIII, IX, and XI

Elevated prothrombotic factors have only recently been associated with primary and recurrent VTE.^{83,139} A dose-response effect has been observed, and elevated factor VIII has been best studied.^{139–141} Factor VIII:C above the 90th percentile is associated with a five times increased risk of VTE.^{141,142} Factor VIII:C elevation is also affected by blood type and race. Elevation of factor XI above the 90th percentile is associated with a twofold increase in VTE, independent of other hypercoagulability factors.¹⁴³ Similar increases in VTE risk have been observed with elevated factor IX.¹⁴⁴ Acquired and environmental factors precipitate VTE in patients with elevation of these factors, as opposed to inherited deficiencies of AT, protein C, and protein S that confer higher VTE risk.¹⁴⁵

The diagnosis is made by the direct measurement of these factors with activity assays. If VTE occurs with one of these factors elevated, standard anticoagulant management should be undertaken.¹³⁷

Disseminated Intravascular Coagulation

DIC is a primary form of acute thrombosis. Causes of DIC include abruptio placentae, gram-positive and gram-negative sepsis, endotoxemia, malignant tumors, pelvic operations, certain snake bites, hematologic malignancies, and hepatic failure.³ Coagulation is activated by the release of TF into the circulation, which activates factor VII to VIIa, leading to massive thrombin production and fibrin generation. Fibrinolysis then becomes activated, leading to bleeding in the later stages of the syndrome because of the consumption of clotting factors, depletion of fibrinogen, and unchecked plasmin activity. Laboratory values in DIC reveal a decline in platelet count and fibrinogen level with a concomitant elevation in fibrin split products and

the presence of a positive D-dimer test. A more chronic form of DIC has been reported, with the release of small amounts of TF into the circulation in conditions such as tumors of the prostate, diabetes mellitus, use of factor IX concentrates, total hip replacement, and abdominal aortic aneurysm.³

Testing for Hypercoagulable States

Patients with a strongly positive family history of thrombotic events, young patients with unprovoked arterial and venous thromboses, and patients with multiple episodes of thrombosis without an underlying anatomic abnormality should be investigated.¹⁴⁶ Whether unaffected relatives should be screened is controversial, and genetic counselors may be of assistance.

A hypercoagulable screen should include routine coagulation tests such as the aPTT and platelet count, AT activity and antigen assay, protein C antigen and activity levels, protein S antigen level, and mixing studies to identify a lupus anticoagulant (if indicated); APC resistance assay and factor V Leiden gene analysis; prothrombin G20210A genetic analysis; homocysteine level; an antiphospholipid antibody screen that includes anticardiolipin antibody; fibrinogen level; factor VIII, IX, and XI levels; and a functional plasminogen assay.

A confirmatory test for dysfibrinogenemia includes a fibrinogen clotting activity-to-antigen ratio. It may also be detected by a prolonged thrombin clotting time (TCT) or reptilase time.¹⁴⁷ Abnormal plasminogens are detected by the presence of reduced activity-to-antigen ratios. PAI-1 levels have to be measured directly by activity or antigen assay. Lipoprotein(a) levels are measured in serum.

BLEEDING DISORDERS

Although the surgeon deals more often with procoagulant states than bleeding disorders, it is important to recognize these disorders when they occur.

Coagulation Factor Deficiency

- 5 Coagulation factor deficiency states are important causes of bleeding, and the most common are factor VIII and IX deficiency states, termed hemophilia A and B, and type I von Willebrand disease (vWD).

Hemophilia A is inherited as a sex-linked recessive deficiency of factor VIII, with fewer cases secondary to spontaneous mutation. The incidence of this abnormality is approximately 1 in 10,000 births. Clinical findings range from bleeding into joints and muscles, epistaxis, hematuria, and bleeding after minor trauma, to prolonged postoperative bleeding, retroperitoneal bleeding, and intramural bowel hemorrhage. Laboratory screening tests usually reveal a prolongation of the aPTT along with decreased factor VIII levels; other test results are normal. The minimum level of factor VIII required for hemostasis is 30%, and spontaneous bleeding is uncommon with factor VIII levels greater than 5% to 10% of normal.¹⁴⁸ Levels less than 2% constitute severe, 2% to 5% moderate, and greater than 5% mild deficiency.¹⁴⁹ Severe deficiency with levels less than 1% poses the risk for spontaneous bleeding episodes. Although the half-life of factor VIII is 2.9 days in normal subjects, the half-life of factor VIII concentrates is only 9 to 18 hours.³ Levels between 80% and 100% of normal should be attained for surgical bleeding or life-threatening hemorrhage. Acquired deficiency has been reported to occur with the development of antibodies to factor VIII after therapy. Inhibitor antibodies develop in approximately 10% to 15% of patients with hemophilia A, although the incidence of antibody formation may be much higher in previously untreated patients and in those with severe hemophilia A.

Recombinant factor VIII preparation has been developed and tested in children and infants. Despite the development of low levels of inhibitors in 20% of children at a mean 9 days after first administration, these inhibitors either disappeared or remained at low levels.¹⁵⁰ Because this recombinant preparation is virus free, the benefits outweigh the risks of low levels of inhibitor development for the treatment of hemophilia A.¹⁵¹

Factor IX deficiency (Christmas factor), known as hemophilia B, is transmitted as an X-linked recessive trait. It also may be acquired because of enhanced factor IX clearance in states such as the nephrotic syndrome, abnormal protein production in vitamin K deficiency, and acquired specific inhibitors to factor IX in various autoimmune diseases, such as SLE. It is clinically indistinguishable from hemophilia A, and laboratory screening tests reveal a prolonged aPTT, with other test results normal, although a greater proportion of patients have only mild or moderate deficiency.¹⁵² Severe deficiency (approximately 30% of cases) is defined as a level of activity less than 4% of normal, whereas moderate deficiency is reported with activity levels between 20% and 40%.³ Treatment consists of plasma or factor IX concentrates and vitamin K. It has been recommended that levels greater than 30% be achieved for hemostasis.¹⁴⁸

vWF causes platelet adhesion to collagen, initiating platelet plug formation. It also forms a complex with factor VIII in the blood. Produced in endothelial cells and megakaryocytes (compared with the liver for factor VIII), it has a circulating half-life of 6 to 20 hours.³ vWD, a deficiency of vWF, is the most common of the inherited coagulation disorders. A number of different subtypes have been identified for its deficiency state, and the syndrome is transmitted as both autosomal dominant (heterozygous) and autosomal recessive (homozygous) forms. Variants include types I and III (quantitative decreases in normal-appearing vWF) and type II (qualitative abnormalities in structure and function of vWF).¹⁵³ vWF deficiency is probably as common as hemophilia A, although the true incidence may surpass what is generally appreciated because many mild cases probably remain undiagnosed.

The classic syndrome is caused by a reduction of factor VIII activity (although not as great as in hemophilia A) and vWF (vWF-factor VIII complex). Clinical manifestations include easy bruisability, mild to moderate epistaxis, gingival bleeding, menorrhagia, rare joint or muscle bleeding, prolonged bleeding following surgery, and subcutaneous bleeding.¹⁵³ Spontaneous bleeding is not as common as in hemophilia A.

Abnormal laboratory tests include a prolonged bleeding time, a decreased level of factor VIII activity, decreased immunoreactive levels of the vWF, and an abnormal platelet aggregation response to ristocetin.³ The most reliable source of vWF is cryoprecipitate, although many concentrates of factor VIII have vWF present and show promise. Desmopressin acetate (DDAVP) is available for the treatment of mild cases of type I and of type IIa and IIb vWD; serum levels of 25% to 50% are needed for hemostasis.¹⁴⁸ In other type II states and type III vWD, factor VIII concentrates are necessary. Recombinant factor VIII/vWF concentrates that avoid the infectious risks of transfusion are available.

Rare Factor Deficiencies

Other specific factor deficiencies are much less common and receive only a brief mention here. These include factors II, XI, V, VII, and X. These can be measured by serum assays, although this is not routinely available in many hospitals. The treatment is primarily fresh frozen plasma concentrates to give back the clotting factors.³

Deficiencies of fibrinogen can also lead to bleeding disorders. This is the only factor deficiency state in which the TCT is prolonged. It is generally believed that a fibrinogen level of 100 mg/mL should be achieved to stop bleeding related to

fibrinogen abnormalities. Fibrinogen deficiency may also occur from consumption during DIC and from primary fibrinolytic states.

Platelet Disorders

Platelet disorders are another important cause of bleeding. Inherited defects of platelet receptors include defects of GpIIb/IIIa (Glanzmann thrombasthenia), characterized by impaired platelet binding to vWF, fibrinogen, and fibronectin. In patients with defects in GpIb (Bernard-Soulier syndrome), the absolute number of platelets is decreased, the platelets are larger, and platelet aggregation and adhesion are abnormal.³ Acquired deficits occur in uremia; both GpIb and GpIIb/IIIa receptors are defective, resulting in impaired adhesion and aggregation. Acquired deficits also occur in patients who previously received platelet transfusions and then acquire immune-mediated antiplatelet antibodies.

Abnormalities in Fibrinolysis

Abnormalities in fibrinolysis may play a role in abnormal bleeding disorders. Genetic or acquired deficiencies in α_2 -AP may be associated with bleeding, whereas deficiencies in factor XIII (fibrin stabilizing factor) may lead to highly lysable clot. α_2 -AP deficiency is treated with ϵ -aminocaproic acid or tranexamic acid. Homozygous patients with factor XIII deficiency and less than 1% of normal plasma activity often show bleeding from the umbilical cord at birth, bleeding after trauma or surgery, and delayed bleeding 24 to 36 hours later.³ Intracranial bleeding also has been noted. Screening test results include a shortened euglobulin lysis time.³ A specific assay for factor XIII activity exists. Treatment consists of fresh frozen plasma, cryoprecipitate, and factor XIII concentrates.

PHARMACOLOGIC AND NONPHARMACOLOGIC INTERVENTIONS

Heparin, Factor Xa, and Direct Thrombin Inhibitors

- 4 Heparin, discovered by Jay McLean in 1916, is a heterogeneous mixture of sulfated polysaccharide molecules of varying molecular weights, ranging from 2 to 40 kD. Heparin is obtained from beef lung or porcine intestine. Heparin accelerates the inhibition of thrombin and other serine proteases by AT. Heparin also directly binds and inhibits coagulation proteases and is important for the selective inhibitor of thrombin, heparin cofactor II.¹⁵⁴ After bolus injection, heparin's half-life is approximately 90 to 120 minutes, although the half-life depends on the amount injected—the more injected, the longer the half-life. Activated factor X and activated factor II are most sensitive to the heparin-AT complex. Heparin is cleared through the reticuloendothelial system and does not cross the placental barrier. Heparin is reversed with protamine sulfate by direct irreversible binding between the compounds.

Clinical use of heparin is for prophylaxis of, and treatment of, venous and arterial thrombosis.¹⁵⁵ In monitoring heparin, an aPTT 1.5 to 2.0 times control or a TCT two times control reflects adequate anticoagulation. Activated clotting times (ACTs) in a range of 150 to 200 seconds also suggest adequate anticoagulation. The use of low-dose unfractionated heparin (UFH) therapy is most commonly used for VTE prophylaxis.⁶³

Because of the bleeding complications caused by UFH, LMWH for venous thrombosis prophylaxis and treatment is

now primary.⁶³ Standard heparin is a mixture of polysaccharide molecules that vary in size from 2 to 40 kD. The anticoagulant effect is primarily centered over the lower end of the molecular-weight spectrum. Standard UFH is able to inhibit thrombin because it is large enough to make a ternary complex between itself, thrombin, and AT. LMWH is not large enough to make this complex because the minimum chain length necessary for formation of such a ternary complex is 18 saccharide units. LMWH demonstrates less AT activity, but for inhibition of factor Xa, such a ternary complex is not necessary. Thus, LMWH preparations are able to inhibit factor Xa. Each LMWH preparation has its own antifactor Xa-to-antifactor IIa (thrombin) ratio, depending on its size and molecular weight.¹⁵⁷ Most commercially available LMWH preparations have ratios between 4:1 and 2:1. Because the bleeding potential of heparin is related largely to its AT activity, LMWH has a lower bleeding potential. In addition, LMWH preparations have less antiplatelet activity and less risk for heparin-induced thrombocytopenia (HIT).

The LMWH preparations have other advantages over standard UFH. These include an improved pharmacokinetic profile due to reduced nonspecific binding to plasma proteins, less lipolysis, a half-life that is not dose dependent, more constant antifactor Xa inhibition, less interference with protein C activation, less complement activation and interference with appropriate platelet aggregation, less risk for osteoporosis, and a lower level of fibrin monomer production.¹⁵⁶ High and sustained plasma antifactor Xa levels exist for greater than 16 hours after LMWH administration in therapeutic doses, and its excretion is primarily renal. There is no available agent effective for complete LMWH reversal as measured by antifactor Xa levels,¹⁵⁷ although clinically the bleeding potential of LMWH can be reversed by protamine sulfate.

LMWH is the primary therapy for VTE. A number of level 1 evidence studies and meta-analyses have compared LMWH with UFH in the treatment of VTE.^{158,159} Together, these studies demonstrate a lower risk of major bleeding, a lower risk of recurrent thromboembolic events, and a lower risk of death than with UFH. Even for nonmassive pulmonary embolism (PE), LMWH appears at least equivalent if not superior to UFH, but much more convenient.¹⁶⁰ It is not necessary to monitor LMWH with coagulation testing except in specific situations such as renal failure, pregnancy, or morbid obesity, and most dosage schemes use either fixed-dose or weight-adjusted dosing given subcutaneously. Because there is no need for coagulation testing, outpatient treatment has become a reality.

LMWH has also been studied in unstable angina¹⁵⁶ and has been found superior to placebo and equivalent or superior to UFH when evaluating the outcomes of death or myocardial infarction, without any increase in major bleeding.

The most common complication of heparin therapy is bleeding. The risk of hemorrhage is increased in the elderly; in postmenopausal women; and in patients with preexisting abnormalities of coagulation, thrombocytopenia, and uremia. Long-term therapy may be associated with alopecia and osteoporosis; osteoporosis has been found in patients receiving large doses of heparin for longer than 6 months.

Reversal of heparin anticoagulation with protamine sulfate may be associated with adverse hemodynamic and hematologic side effects, including hypotension, bradycardia, pulmonary artery hypertension or hypotension, declines in oxygen consumption, leukopenia, and thrombocytopenia.^{161,162} Immunologic reactions may occur in patients with prior exposure to protamine, especially in diabetic patients taking NPH insulin that contains protamine or those previously exposed to protamine. Unfortunately, no other effective and safe agent for heparin neutralization exists, and in those situations when heparin must be reversed, such as at the completion of major aortic reconstructions and cardiopulmonary bypass, protamine must be given. Although it has been suggested that the

rate of administration is the most crucial factor in protamine-related reactions, declines in hemodynamic parameters and oxygen consumption still occur with slow administration.¹⁶²

The specific factor Xa inhibitor pentasaccharide fondaparinux (Arixtra, GlaxoSmithKline, Parsippany, NJ) potentiates approximately 300-fold factor Xa neutralization by AT. It has a half-life of 17 hours and does not bind to plasma proteins. It is primarily excreted through the kidneys. Large prospective randomized studies for both DVT and PE treatment have been conducted suggesting efficacy and safety similar to LMWH.¹⁶³ In orthopedic surgery, this agent is superior to the best currently available DVT prophylaxis using LMWH. In fact, in hip fracture and knee reconstruction surgery, this agent has decreased the incidence of DVT by greater than 50%. In a meta-analysis of more than 7,000 patients, fondaparinux significantly decreased the odds of VTE as compared to LMWH with no difference in critical bleeding, although major bleeding was slightly greater.^{164–166} There is no good reversal drug for this agent, and this has been one of the factors that has prevented its wider adoption into the medical and surgical communities.

Oral Xa inhibitors are currently being developed. Rivaroxaban (BAY 59-7939), one such inhibitor, showed promising results in phase 2 trials when compared to enoxaparin for the prevention of VTE in those undergoing major orthopedic surgery.¹⁶⁷ Trials are currently under way in additional treatment applications.

Direct thrombin inhibitors have been developed for both oral and parental use, particularly in HIT. Unlike heparin, the direct thrombin inhibitors have the ability to inactivate fibrin-bound thrombin.¹⁶⁸ Direct thrombin inhibitors such as argatroban and lepirudin (hirudin analogue) have also been shown to be effective anticoagulants in patients with HIT and are dosed via the aPTT.¹⁶⁹ Argatroban has a relatively short half-life, is cleared by the liver, and is safe to use in those with renal insufficiency. Conversely, lepirudin is cleared renally, has a slightly longer half-life, and is the preferred anticoagulant in patients with hepatic insufficiency. A third parental thrombin inhibitor, bivalirudin is used in patients with unstable angina who are undergoing percutaneous cardiac intervention and cardiac surgery.

Although early trials with ximelagatran, a direct oral thrombin inhibitor, were not successful owing to the hepatic toxicity, a new agent in the same family, dabigatran, has promising data supporting its efficacy and safety. Results of a large phase 2 trial comparing dabigatran to enoxaparin for VTE prevention in those undergoing hip replacement demonstrated noninferiority to enoxaparin.¹⁷⁰

Other new alternative agents are in various stages of development, such as oral heparins, oral factor IIa and Xa inhibitors, P-selectin inhibitors, factor VIIa inhibitors, TFPIs, and PAI-1 inhibitors.¹⁷⁰ These agents, available now and in the future, will likely revolutionize the whole field of thrombosis prophylaxis and treatment.

Heparin-induced Thrombocytopenia and Thrombosis Syndrome

6 A specific complication of heparin deserves detailed discussion. HIT occurs in 0.6% to 30% of patients in whom heparin is given, although severe thrombocytopenia associated with thrombosis (HITTS) occurs much less frequently.^{171,172} Approximately one half of HIT patients have thrombosis that is noted clinically or by duplex imaging. In an analysis of 11 prospective studies, the incidence was reported to be 3%, with thrombosis in 0.9%.¹⁷³ Although earlier morbidity and mortality rates of 61% and 23% had been reported,⁷⁰ with early diagnosis and appropriate treatment, these rates have declined to 6% and 0%, respectively.¹⁷⁴ HIT is caused by a heparin-dependent IgG antibody that, when bound to platelet factor 4

(PF₄), induces platelet aggregation in part by inducing MP formation.^{175,176} The antibody may not be heparin specific, as the degree of sulfonation of the heparinlike compound has been suggested to be critical for this aggregation.¹⁷⁷ Both porcine and bovine UFH as well as LMWH have been associated with HIT.¹⁷⁸ The syndrome usually begins 3 to 14 days after heparin is begun. Both arterial and venous thromboses have been reported, and even small exposures to heparin (heparin coating on catheters) can cause the syndrome.^{171,179}

The diagnosis should be suspected when a patient experiences a 50% or greater decline in platelet count, when there is a fall in platelet count below 100,000/mL during heparin therapy, or in any patient who experiences thrombosis during heparin administration.¹⁸⁰ The syndrome may be difficult to diagnose as many hospitalized patients have multiple reasons for low platelet counts, and vigilance is important. A platelet count should be checked about every 2 days when on heparin therapy.

The laboratory diagnosis of HIT/HITTS is made by a number of assays. The serotonin release assay (SRA) was the “gold standard.” An enzyme-linked immunosorbent assay (ELISA) test detecting the antiheparin antibody in the patient’s plasma directed against the heparin–PF₄ complex is now commonly used.¹⁷¹ This assay is less specific but easier to perform and interpret than the serotonin assay.

When the diagnosis is made (clinically), cessation of heparin is mandatory. This includes removing heparin from intravenous catheters and flushes.¹⁷⁹ Warfarin should not be administered until an adequate alternative anticoagulant has been started to prevent venous limb gangrene development.¹⁸¹ LMWH preparations have high rates of cross-reactivity with the HIT antibody and therefore should not be merely substituted for UFH in patients with HIT.¹⁸²

A number of anticoagulants are now available to substitute for patients with this diagnosis. The direct thrombin inhibitors hirudin (lepirudin/Refludan) and argatroban are the treatments of choice and are U.S. Food and Drug Administration approved for this indication.^{180,183} These agents show no cross-reactivity to heparin antibodies.

Warfarin

Warfarin oral anticoagulant therapy remains the standard for long-term treatment of arterial and venous thromboembolism. Warfarin interferes with the vitamin K–dependent clotting factors II, VII, IX, and X and proteins C and S. In the liver, these factors are γ -carboxylated in a reaction catalyzed by the reduced form of vitamin K. During this reaction, 10 to 12 glutamic acid residues are converted to γ -carboxyglutamic acid residues. When these factors are released from the liver, they are secreted as active proteins.³ The carboxyglutamic acid residues are responsible for these proteins binding to phospholipid membranes and the formation of the Xase and prothrombinase complexes on activated platelet surfaces. Warfarin prevents the reduction of vitamin K once it has functioned as a cofactor for the γ -carboxylation.

Because of variations in the thromboplastins used for the prothrombin time (PT) determinations in various countries, the international normalized ratio (INR) system, in which the sensitivity of thromboplastins has been standardized, was developed.¹⁸⁴ Using this system, the proper range for treatment of most thrombotic diseases by warfarin is an INR of 2 to 3.

Major complications of warfarin therapy include bleeding, recurrent thrombosis, and skin necrosis. Patients at highest risk for bleeding on warfarin include the elderly, patients with gynecologic or urologic disorders, women after childbirth, and patients given large warfarin loading doses. A specific complication of warfarin is skin necrosis, which occurs more frequently in patients with protein C deficiency. This usually involves full-thickness skin sloughing over fatty areas such as

the breasts and buttocks but can also occur in other anatomic distributions such as the extremities and digits.

Warfarin should be continued for at least 3 months after an initial episode of DVT or arterial thromboembolism. Detailed guidelines for level of anticoagulation and duration are updated every 3 to 5 years.⁶³ Currently, 3 months of anticoagulant treatment is indicated for a provoked VTE event, while consideration of bleeding and thrombosis risk needs to be determined and a longer duration used if an unprovoked event occurred. Male gender, antiphospholipid syndrome, prior DVT, and thrombophilias all increase the risk of recurrence and support prolonged anticoagulation. Conversely, Asian race and a normal D-dimer at 1 month after ceasing anticoagulation support limited anticoagulation. Data that support prolonged therapy for unprovoked DVT include a recent multicenter trial comparing low-dose warfarin (INR 1.5 to 2.0) to placebo with 4-year follow-up.¹⁸⁵ Another study suggested that full-dose warfarin (INR 2.0 to 3.0) was superior to low-dose warfarin in these same patients without a difference in bleeding, suggesting that unprovoked DVT requires long-term oral anticoagulation of some still-to-be-defined duration.¹⁸⁶

Antiplatelet Agents

Antiplatelet agents are used to prevent cardiovascular events such as coronary and peripheral arterial thrombosis. Platelet aggregation can be inhibited by several mechanisms, including (a) blocking cyclooxygenase, the first step in converting arachidonic acid to thromboxane and prostacyclin; (b) blocking thromboxane synthase, the enzyme leading to thromboxane A₂; (c) blocking the thromboxane A₂ receptor; (d) increasing intraplatelet levels of cyclic adenosine monophosphate (cAMP) or guanosine monophosphate (GMP), which inhibit the exposure of the platelet GpIIb/IIIa receptor; and (e) directly blocking the platelet receptor GpIIb/IIIa.

Aspirin inhibits cyclooxygenase, and thus both thromboxane and prostacyclin. In clinical situations, the use of lower doses of aspirin in an attempt to inhibit thromboxane generation but preserve prostacyclin generation is theoretical, and may have some efficacy. Dipyridamole (Persantine; Boehringer Ingelheim, Ridgefield, CT), inhibits the uptake of adenosine into platelets, endothelial cells, and red blood cells. This leads to increased platelet cAMP levels through a local increase in adenosine concentration, inhibiting platelet aggregation. Additionally, it also inhibits phosphodiesterase, the enzyme that normally degrades cAMP, leading to higher levels of cAMP, and augments the increase in cGMP produced by nitric oxide. Thienopyridines work by ADP receptor blockade, interfering with subsequent GIIb/IIIc fibrinogen binding.¹⁸⁷ In addition, monoclonal antibodies to GpIIb/IIIa itself or synthetic peptide blockers of this receptor containing the RGD sequence or the fibrinogen γ -chain carboxyl-terminal sequence directly inhibit the function of this receptor. Receptor blockage is the most specific way to inhibit aggregation, and when the GpIIb/IIIa receptor is blocked, even high concentrations of agonists cannot stimulate platelets.

Because of ticlopidine-associated neutropenia, an analogue of ticlopidine, clopidogrel, was developed. This thienopyridine compound is not associated with the same degree of neutropenia and has been shown to reduce the composite endpoints of stroke, myocardial infarction, and death in patients with vascular disease.² It is mandatory treatment for patients in whom a drug-eluting stent has been placed in the coronary arterial circulation and is used for periprocedural protection in those patients undergoing peripheral angioplasty and stenting.

Direct inhibitors of the GpIIb/IIIa receptor were first developed as murine-derived monoclonal antibodies. The compound C7E3Fab (ReoPro; Eli Lilly, Indianapolis, IN), a human chimeric monoclonal antibody directed at GpIIb/IIIa, is the

first agent of this class to become clinically available.² Its receptor binding is nonspecific and it binds to other cell surface integrins. Other agents include RGD mimics that are competitive antagonists to the GpIIb/IIIa receptor, including the cyclic peptide eptifibatide (Integrilin; Key Pharmaceutical, Kenilworth, NJ) and the parenteral nonpeptide mimetics tirofiban (Aggrastat; Merck & Co., West Point, PA) and lamifiban.¹⁸⁸ All studies to date with these agents have involved coronary interventions.

Fibrinolytic Agents

Fibrinolytic agents are direct or indirect activators of plasminogen, the inactive proteolytic enzyme of plasma that binds to fibrin during the formation of thrombus. Fibrin-bound plasminogen is more susceptible to activation than is free plasminogen in plasma. Streptokinase isolated from group C β -hemolytic streptococci and acylated plasminogen-streptokinase (APSAC) act through a streptokinase-plasminogen complex; urokinase, single-chain urokinase-type plasminogen activator (SCU-PA), and recombinant tPA act directly on plasminogen without an intermediate drug-plasminogen complex¹⁸⁹ (Fig. 5.11). tPA (originally isolated from a melanoma cell line and now produced through recombinant DNA technology), APSAC, and SCU-PA are termed *fibrin selective* because of their high ratio of activity for fibrin-bound plasminogen compared with circulating plasminogen. For therapeutic uses, tPA or recombinant plasminogen activator (rPA) is primarily used, and the others are of historical significance only. tPA has a fibrin-binding site and a catalytic site that are widely separated from each other. This separation allows tPA to be activated to its fibrin target, thus establishing its fibrin-specific nature. Evidence-based recommendations for agent and indications are continually updated.^{190,191}

Bleeding complications associated with fibrinolytic agents are related to the invasive procedures associated with drug delivery. Factors associated include hypofibrinogenemia and fibrin degradation products. The latter inhibit fibrin polymerization and, in combination with a decrease in the clotting factors V and VIII (from excess plasmin not neutralized by α_2 -AP), inhibit the ability of blood to clot. Although coagulation tests in general do not correlate well with bleeding, a fibrinogen level less than 100 mg/dL is associated with an increased risk and severity of bleeding.

Platelets are both inhibited and stimulated by fibrinolytic agents. Because fibrinogen is a necessary cofactor for ADP-induced platelet aggregation, low fibrinogen levels aggravate a platelet defect. At the same time, plasminogen bound to platelets leads to impaired adhesion and a decrease in their ability to aggregate. Plasmin-induced cleavage of adhesive proteins, such as thrombospondin, fibronectin, and fibrin, also disrupts the bonds that hold platelet aggregates together.

Despite these mechanisms that decrease the clotting ability of blood during fibrinolytic therapy, it has been found that these agents promote reocclusion in up to 30% of cases early after thrombolysis through platelet activation, suggesting that platelet activation occurs early after lysis and platelet inhibition occurs later.¹ In addition, increased synthesis of endothelial cell PAI-1 has been demonstrated experimentally after treatment with tPA, another mechanism that could potentially contribute to early thrombotic reocclusion if the patients are not heparinized.¹⁹²

Thrombolytic therapy for peripheral arterial applications is commonly used, especially when the agents are given via catheter infusion, and is a standard treatment for acute limb ischemia and peripheral bypass graft occlusion.¹⁹³ Several studies suggest its efficacy and safety for acute limb ischemia as comparable to surgery.^{194,195} After thrombolytic therapy has reopened an occluded vessel or graft, however, radiologic or surgical correction of the lesion responsible for the thrombosis

FIGURE 5.11. Sites of action of plasminogen activators on plasminogen. APSAC, acylated plasminogen–streptokinase; Plgn, plasminogen; SCU-PA, single-chain urokinase plasminogen activator; SK, streptokinase; TPA, tissue plasminogen activator; UK, urokinase.

must be addressed for long-term success.¹⁹⁶ The use of intra-operative thrombolytic therapy has been advocated for situations in which complete clot evacuation cannot be accomplished (as may occur in up to 40% of patients undergoing balloon embolectomy with an embolectomy catheter for acute arterial occlusion) or when the distal vasculature is occluded and precludes appropriate inflow patency.¹⁹⁷

Complications associated with thrombolytic therapy for arterial thrombosis include bleeding, rethrombosis, embolization treated with further thrombolytic therapy, and sepsis from prolonged catheter placement. The most recent innovation in intra-arterial thrombolytic therapy involves lacing the entire length of the thrombus with high-dose tPA before continuous infusion and then using pulse-spray techniques, sometimes in conjunction with mechanical dissolution.¹⁹⁸

Indications for DVT and PE thrombolytic therapy remain controversial.¹⁹⁷ Thirteen studies of thrombolytic therapy for acute DVT have been compiled from the literature.¹⁹⁹ In these studies, patients were assessed with venography. Of those patients treated with anticoagulants, only 4% had complete lysis and 14% revealed partial lysis. In contrast, 45% of patients treated with thrombolytic agents showed significant or complete clot lysis and an additional 18% revealed partial lysis. Importantly, catheter-directed thrombolysis for iliofemoral DVT is associated with significantly improved quality of life over time.²⁰⁰ Thrombolytic therapy in PE has been extensively studied. Early studies evaluated the use of either urokinase or streptokinase. Although both agents rapidly lysed clot and improved pulmonary hemodynamics, there was no difference in patient mortality rate or recurrence rate of PE compared with heparin alone.^{201,202} As a general guide, thrombolytic therapy for PE should be considered when there is angiographically documented lobar or greater PE causing acute pulmonary hypertension and right ventricular failure with hemodynamic compromise; lesser degrees of PE should be treated with standard heparin or LMWH anticoagulation.^{63,203} Fibrinolytic therapy may also have a role and has been suggested for use in upper extremity effort thrombosis, catheter-induced venous thrombosis, and superior vena caval thrombosis. Contraindications to thrombolytic therapy, whether regional or systemic, are well defined (Table 5.4).

TABLE 5.4 INDICATIONS/CONTRAINDICATIONS

CONTRAINDICATIONS TO THROMBOLYTIC THERAPY

ABSOLUTE

- Neurosurgery within 3 mo
- Active internal bleeding
- Recent (<2 mo) cerebrovascular accident
- Intracranial disease
- Recent gastrointestinal bleeding

RELATIVE

Major

- Recent (<10 d) major surgery, obstetric delivery, or organ biopsy
- Left heart thrombus
- Active peptic ulcer or gastrointestinal abnormality
- Recent major trauma
- Uncontrolled hypertension (systolic >180 mm Hg; diastolic >110 mm Hg)
- Recent eye surgery

Minor

- Minor surgery or trauma
- Recent cardiopulmonary resuscitation
- Atrial fibrillation with mitral valve disease
- Bacterial endocarditis
- Hemostatic defects (i.e., renal or liver disease)
- Diabetic hemorrhagic retinopathy
- Pregnancy

CONTRAINDICATIONS TO STREPTOKINASE

- Known allergy
- Recent streptococcal infection
- Previous therapy within 6 mo

Table adapted from TASC II. *J Vasc Surg.* 2007;45:S45.

Dextran

Dextran is a high-molecular-weight polysaccharide produced from sucrose by *Leuconostoc mesenteroides*. Fractionation and hydrolysis produce a product with an average molecular weight of either 40 kD (dextran-40 [Rheomacrodex; Medisan, Parsippany, NJ]) or 70 kD (dextran-70). Dextran-40 has been studied in detail for its ability to augment patency of difficult lower extremity bypass grafts in the early postoperative period. Dextran-40 acts as a volume expander, causing hemodilution, decreasing blood viscosity, decreasing platelet adhesiveness, reducing factor VIII activity, and increasing the lysability of clots.²⁰⁴ In addition, dextran has been found to coat endothelial cell surfaces, decreasing their electronegativity.

LABORATORY MONITORING OF COAGULATION AND ANTICOAGULATION

Tests of Platelet Function

Platelet tests include peripheral platelet counts, bleeding times, and platelet aggregation. Usually, a platelet count of 50,000/mL or more ensures adequate hemostasis, whereas counts less than 10,000/mL are dangerous and may lead to spontaneous bleeding. Thrombocytosis is considered to exist when the platelet count exceeds 500,000/mL, although in some cases (especially those involving myeloproliferative disorders or following splenectomy), counts may be greater than 1,000,000/mL.³ Bleeding time assays assess the ability of platelets to form hemostatic plugs and are usually shorter than 8 minutes. A bleeding time between 8 and 15 minutes most often reflects a low plasma level of vWF, the use of antiplatelet drugs, the presence of lupuslike antibodies, or a factor XI deficiency.³ A bleeding time greater than 15 minutes is clearly prolonged and indicates severe platelet functional impairment, very low levels of vWF, or a fibrinogenemia and severe factor V deficiency. Many of the platelet functions are best assessed with the platelet function analyzer (PFA-100; Dade Behring, Germany), available in most hospitals.²⁰⁵

Coagulation Tests

Coagulation tests include PT (intrinsic and extrinsic pathways and fibrinogen), aPTT (contact and intrinsic pathway), TCT (fibrinogen conversion to fibrin), and ACT (whole blood and platelets). The only abnormality that causes an isolated elevation in PT with all of the other test results normal is factor VII deficiency. In addition, the PT is sensitive to small decreases in factor V levels. The aPTT identifies abnormalities of the contact and intrinsic phases of coagulation. Conditions that cause a prolonged aPTT include the presence of heparin; deficiencies in factors VIII, IX, and XII; and the presence of lupuslike anticoagulants.³ aPTT values have variably been shown to correlate with heparin dosages and serum heparin levels, and levels of 0.2 IU/mL or greater usually correlate with an aPTT of 1.5 times normal or greater.

The TCT is a measurement of the time it takes for exogenously added thrombin to turn plasma fibrinogen into fibrin clot. As such, it is extremely sensitive to levels of heparin and is an excellent means of measuring the level of heparin-induced anticoagulation. The beauty of the TCT is that it is not specific for any disease condition; thus, it may be used to differentiate factor deficiencies from the presence of heparin or to separate lupus anticoagulant from abnormalities in fibrinogen levels.³

The ACT is a measurement of the ability of whole blood to clot and as such is an available technique for monitoring

intraoperative heparin levels. The ACT responds linearly to increasing heparin dosage and correlates well with observed clinical anticoagulation (thrombus-free surface on cardiopulmonary bypass devices).²⁰⁶ Adequate anticoagulation for extracorporeal circulation is defined as an ACT of 480 seconds or more, but most cardiovascular surgeons would agree that any value between 300 and 600 seconds is acceptable. For peripheral vascular applications, values of 250 seconds or greater are considered appropriate levels, representative of full intraoperative anticoagulation. The ACT may be affected by hemodilution, cardioplegia solutions, hypothermia, platelet dysfunction, hypofibrinogenemia, and other coagulopathies, as well as by certain medications and excess protamine administration. Finally, factor Xa levels can be measured to accurately measure LMWH or direct Ia inhibitors. Clinically, this is useful in renal failure patients and morbidly obese patients.

Tests of Fibrinolysis

Tests of fibrinolysis are less well characterized. The euglobulin lysis test time is a crude screening test for problems with fibrinolysis.³ Patients with accelerated fibrinolysis are often found to have a deficiency of α_2 -AP (of which the total amount normally is only half of the total plasmin that can be generated) or the fibrin clot-stabilizing factor XIII.³ A deficiency of PAI-1 also may lead to accelerated fibrinolysis. During normal clot formation and breakdown, the D-dimer fragment of fibrinogen is a marker for ongoing thrombosis and physiologic fibrinolysis, whereas for fibrinogenolysis, the two D fragments that are produced are not cross-linked into the D-dimer form.³

CHAPTER 6 ■ INFLAMMATION

MATTHEW R. ROSENGART AND TIMOTHY R. BILLIAR

KEY POINTS

- 1 Innate immunity, a system already poised to respond prior to any stimulus, provides the initial defense against microbes. Subsequent reinforcement is provided by the more specific adaptive immune system, which possesses exquisite specificity for subsequent exposure to individual microbes and the capacity to learn and modify subsequent responses to repeated exposures. Both are composed of cellular and humoral components.
- 2 Implicit with the capacity for pathogen elimination is the potential for destruction of host tissues. Numerous regulatory mechanisms provide temporal and spatial control of the inflammatory processes, including programmed cell death (i.e., apoptosis).
- 3 The T_H1 inflammatory response (i.e., cell-mediated immunity or delayed-type hypersensitivity) is induced by interleukin-12 (IL-12) derived from phagocytes and provides one major arm of the adaptive immune response; it is mediated by $CD4^+$ and $CD8^+$ lymphocytes and macrophages, which regulate production of opsonizing and complement fixing antibodies and are effectors of phagocyte-dependent responses.
- 4 The principal stimulus for T_H2 differentiation is IL-4, which is derived from T cells, mast cells, and basophils. As the cellular effectors of humoral immunity, they provide the other major arm of the adaptive immune response, which is mediated by T_H2 $CD4^+$ cells, B cells, plasma cells, and antibodies.
- 5 Over 30 randomized controlled clinical trials have been conducted to assess the efficacy of agents modulating inflammation, in particular systemic cytokine concentrations, in reducing mortality. Yet only one, activated protein C, has been approved by the U.S. Food and Drug Administration for use, and studies are ongoing to confirm its benefit.
- 6 The complement system is integral to both innate and adaptive immunity and has the capacity to independently eliminate organisms and facilitate host defense by marking foreign particles for phagocytosis through opsonization.
- 7 Additional systems, including the vascular (i.e., vasodilatation), adhesion receptors, kinin cascade) and neuroendocrine (i.e., adrenocorticotrophic hormone, arginine vasopressin, corticotropin-releasing hormone), integrate with the immune system, sharing similar mediators and their receptors, to orchestrate an intense, coordinated response to any injurious/septic insult.
- 8 Our immune system differentiates pathogens and damaged cells from self using evolutionarily ancient sets of recognition molecules called pattern recognition receptors, which bind conserved molecular structures found in large groups of pathogens, termed pathogen-associated molecular patterns (PAMPs), an example being the Toll-like receptors (TLRs).
- 9 Danger-associated molecular patterns are the endogenous equivalent of PAMPs, represent danger signals or “alarmins,” and share many characteristics similar to cytokines. They may be released following nonprogrammed cell death, such as necrosis, or secreted as mediators by immune cells, under which circumstance they may facilitate the inflammatory response.

The concept of inflammation has undergone considerable revision since the initial description of the four cardinal signs and symptoms by Celsus in the first century AD: “*rubor et tumor cum calor et dolore*,” redness and swelling with heat and pain.¹ Centuries lapsed before John Hunter postulated that inflammation provides a survival mechanism to preserve the host. Ironically, he commented that an exuberant inflammatory response could be deleterious; the pathologic sequelae of excessive inflammation (i.e., acute respiratory distress syndrome [ARDS], multiple organ dysfunction syndrome [MODS]) are encountered more frequently as technology affords survival of the initial insult.¹ The 19th century witnessed milestone contributions to our understanding of this process. Rudolph Virchow detailed the cellular pathology of inflammation, Julius Cohnheim provided microscopic details of the acute phases of inflammation (vasodilatation, edema formation, and leukocyte emigration), and Elie Metchnikoff described the events of phagocytosis.^{1–3} The evidence culminated into a cellular and humoral concept of inflammation, both of which were deemed critical in host defense against foreign pathogens.

In the 20th century, technologic advancements in molecular biology and biochemistry facilitated more detailed investigation and enabled the rapid expansion of knowledge of the many interwoven facets of the inflammation process. Evidence

began to accumulate that the ramifications of these processes extended beyond the confines of the insult. Many humoral mediators, in addition to local effects, influenced distant targets as well, such as the liver and neurohormonal centers. Recently, it has become clear that the immune system, endocrine system, and nervous system comprise an integrated network sharing similar mediators and their receptors. Such an integrative view, introduced by J. Edwin Blalock, when combined with Hans Selye’s concept of stress, led to the contemporary understanding of sickness behavior, defined by Robert Dantzer as a highly organized strategy of the organism to fight infections and to respond to other environmental stressors. Hence, what originated nearly two millennia ago as a simple concept founded on a constellation of signs and symptoms now is considered an intense, coordinated interplay of the nervous, vascular, endocrine, and immune systems to any injurious insult. It is the culmination of millions of years of evolution. Without it, life would be an arduous, painful, and brief existence, at best.

This chapter attempts to summarize this enormous quantity of information. An initial description of the elements involved in inflammation will provide the foundation upon which to discuss the sequence of events and interactions that comprise the inflammatory cascade.

INNATE VERSUS
ADAPTIVE IMMUNITY

1 The initial security against microbes is the responsibility of our innate immunity, a system composed of both cellular and humoral components, already poised to respond prior to any stimulus.⁴ Phylogenetically it is ancient and conserved, notably providing the primary mechanism of invertebrate host defense. The response it provides is uniform and consistent with each successive infection. Subsequent reinforcement is provided by the more specific and targeted efforts of the adaptive immune system. In contrast to innate immunity, subsequent exposure to the inciting agent during adaptive immunity elicits responses of increased magnitude and defensive capabilities.⁴ This exquisite specificity for individual microbes, the capacity to “learn,” “remember,” and modify subsequent responses to repeated exposures, has provided the impetus for the name.

Both arms of immunity are composed of cellular and serum components. In the adaptive immune response this has been divided into humoral immunity, which is mediated primarily by antibodies, and cell-mediated immunity. These are not distinct systems and form an integrated system of host defense.

CELLULAR COMPONENTS

Neutrophils

Neutrophils are integral to both innate and humoral immunity, providing the initial defense against invading viral, bacterial, and parasitic pathogens. This importance is underscored by the fact that 55% to 60% of the hematopoietic output of bone marrow is dedicated to the production of neutrophils.⁵ On exiting the marrow they circulate for 7 to 10 hours before taking up residence in the tissues for 1 to 2 days (Table 6.1).^{6,7} They are uniquely sensitive to minute concentration gradients of microbial products and inflammatory mediators and rapidly accumulate at sites of infection, where they ingest and dispose of a wide array of pathogens with their vast microbicidal armamentarium. This pathogenicity, however, carries with it an implicit capacity for host injury and, accordingly, neutrophil function must be tightly regulated.

Recruitment. Neutrophil recruitment may be viewed as a sequence of events progressing from initial adhesion to activated endothelium, to subsequent extravasation and emigration toward inflammatory foci, to the ultimate elimination of foreign microorganisms through phagocytosis, to the generation of reactive oxygen species and the release of microbial substances.⁴ These processes function in a similar context in

other inflammatory cells that migrate to foci of infection or inflammation.

After injury, local and regional vasodilation induces hyperemia and facilitates the delivery of leukocytes. Extravasation of plasma creates edema, and in combination with the release of vasoactive substances leads to hemoconcentration, which promotes the peripheral margination of leukocytes.^{8,9} Circulating neutrophils transiently interact with the endothelial cell surface molecules during “rolling,” a process that involves a series of loose and reversible attachments (Fig. 6.1). These interactions are prerequisite for subsequent tighter interactions. The family of selectin receptors binds with their counterligands, the sialyl Lewis family, and other fucosylated and sulfated structures and mediate this process. E-selectin and P-selectin are present on endothelium and L-selectin is found on leukocytes.⁴

Consequent to stimulation with inflammatory mediators (thrombin, histamine, complement fragments, oxygen species, lipopolysaccharide [LPS], and cytokines such as interleukin-1 [IL-1], tumor necrosis factor- α [TNF- α], and interferon- γ [IFN- γ]), vascular endothelial cells express P- and E-selectin, which may engage the neutrophil surface glycoprotein P-selectin glycoprotein ligand 1 (PSGL-1) or sialyl Lewis. P-selectin is stored intracellularly and can be rapidly mobilized for expression within minutes of cellular activation. Endothelial cells also translocate ligands for neutrophil L-selectin and release mediators like platelet-activating factor (PAF) and IL-8. Cytokines such as TNF- α , granulocyte-macrophage colony-stimulating factor (GM-CSF), and granulocyte colony-stimulating factor (G-CSF) increase the affinity of leukocyte L-selectin for its counterreceptor. In addition to mechanical anchorage, these selectins induce signal transduction pathways that influence cellular function. P-selectin facilitates neutrophil degranulation and superoxide production, and cross-linking L-selectin primes the neutrophil for increased superoxide production.^{10–12}

After rolling, L-selectin is rapidly shed in preparation for leukocyte diapedesis and emigration. Subsequent exposure to chemoattractant gradients results in conversion of the neutrophil to a state of tight stationary adhesion (Fig. 6.1). The receptors mediating this interaction are members of the β_2 -integrin family, most importantly leukocyte function antigen 1 (LFA-1, CD11a/CD18) and Mac-1 (CD11b/CD18), and their expression is enhanced in response to selectin binding. Secretory vesicles are a major reservoir for these receptors. Both integrin receptors engage the intercellular adhesion molecules (ICAM)-1 and ICAM-2 in mediating adhesion; yet, each provides additional important functions. Leukocyte emigration is primarily an LFA-1-dependent process, as mice deficient in this receptor show reduced neutrophil attachment to ICAM-1 and endothelial cells. By contrast, mice lacking Mac-1 demonstrate impaired degranulation, superoxide production, and

TABLE 6.1

LEUKOCYTE SUBSETS

■ CELL	■ NEUTROPHIL	■ MONOCYTE	■ LYMPHOCYTE	■ EOSINOPHIL	■ BASOPHIL
Size (μm)	13	16–20	9–16	12–16	15

Life span	6 h to 7 d	1 d to years	Months to years	8 to 12 d	1 year
Activators	G-CSF, IL-8	M-CSF, GM-CSF, IFN- γ , TNF- α	IL-2, IL-12 (T_H1), IL-4 (T_H2)	G-CSF, IL-5	G-CSF, IL-3
G-CSF, granulocyte colony-stimulating factor; IL, interleukin; M-CSF, macrophage colony-stimulating factor; T_H , helper T cell; TNE, tumor necrosis factor. Modified from Burkitt G, Young B, Heath JW, eds. <i>Wheater's Functional Histology: A Text and Colour Atlas</i> , 3rd ed. Edinburgh, New York: Churchill Livingstone; 1993.					

FIGURE 6.1. Leukocyte recruitment. 1. Circulating leukocytes express integrins in a low-affinity conformation. 2. Exposure to activated endothelium leads to rolling, which is mediated by L-selectin and P-selectin on the neutrophil and E-selectin on endothelium. 3. Leukocyte exposure to cytokines released by macrophages phagocytosing pathogens induces a high-affinity integrin conformation. Tight leukocyte-endothelial adhesion involves integrin engagement with counterligand expressed on the endothelium. 4. Subsequent exposure to chemokines leads to diapedesis, which is further mediated by the family of β_1 and β_2 integrins. (Redrawn from Abbas AK, Lichtman AH. *Cellular and Molecular Immunology*. Philadelphia: Saunders; 2003.)

phagocytosis. Mac-1 also binds fibrinogen, heparin, and factor X and is implicated in neutrophil phagocytosis-induced apoptosis, a process essential for resolution of the inflammatory process (vide infra). The very late antigen 4 (VLA-4) binds vascular cellular adhesion molecule 1 (VCAM-1) and may provide an additional mechanism for tight adhesion. In addition to providing mechanical anchorage, these receptors interact with the cytoskeleton and other structural proteins and signaling cascades and are thought to represent a biochemical link between the external environment and intracellular signal transduction cascades that induce a cellular phenotype more appropriate for the current environment (Box A. Integrin signaling).^{13–15}

Once tightly adhered, neutrophils must diapedese between endothelial cells and across the basement membrane to arrive at the focus of inflammation. Platelet/endothelial cell adhesion molecule 1 (PECAM-1) and integrin-associated protein are integral to transmigration (Fig. 6.1).^{13,14,16,17} PECAM-1 is concentrated along the intercellular junctions of endothelial cells, and both leukocyte and endothelial PECAM-1 appear to be essential for neutrophil and monocyte diapedesis. Other candidate receptors include the β_1 integrins, or VLAs, which possess affinity for many constituents of the extracellular matrix, including laminin, fibronectin, and collagens, and the β_3 family of integrins including glycoprotein (Gp) IIb/IIIa and the vitronectin receptor.⁴ Further “directions” for migration to the focus of inflammation are delivered by the concentration gradients of chemotactic factors, including complement C5a, IL-8, leukotriene B₄ (LTB₄), and the bacterial product formyl-methionyl-leucyl-phenylalanine (fMLP).^{18–20}

The clinical significance of even minor derangements in any aspect of this process is evident in the disease leukocyte adhesion deficiency, characterized by complete absence of CD18, and therefore all β_2 integrins. Patients usually succumb to recurrent skin and mucosal infections within the initial 10 years of life.⁴

Phagocytosis. Microbial elimination commences when the neutrophil first encounters foreign pathogen. It is facilitated by opsonization, a process whereby microbes are coated by

immune globulins and/or complement, which subsequently bind to their respective cell surface receptors, Fc γ Rs and Mac-1.^{21–23} Neutrophils constitutively express low-affinity immune globulin receptors Fc γ RII and Fc γ RIII and can be induced to express high-affinity Fc γ RI by incubation with IFN- γ or cross-linking β_2 integrins.^{5,24} Complement-dependent phagocytosis is mediated by interactions between the leukocyte Mac-1 receptor and the complement opsonin iC3b.

Once engaged, Fc γ Rs are phosphorylated on tyrosine residues within an immunoreceptor tyrosine activation motif (ITAM) by the Src family of kinases.²⁴ These phosphorylated sites serve as docking regions for a variety of proteins, in particular Syk. The importance of Syk is underscored by the observation that mice deficient in Syk are incapable of ingesting IgG-opsonized particles. A series of enzymes are subsequently activated including phosphoinositol 3-kinase, phospholipase C, and protein kinase C. Ultimately, the actin cytoskeleton undergoes rearrangement and the local plasmalemma is remodeled in the formation and sealing of the phagosome.^{4,24}

This immature phagosome undergoes a series of maturation steps, whereby it acquires the machinery necessary for the killing and disposal of internalized microorganisms. Alterations in cytosolic calcium concentration induce the fusion of secretory vesicles and granules containing the microbicidal armamentarium with the immature phagosome.²⁴ Proteins effected by calcium concentration and that may govern phagosomal maturation include synaptotagmins, actin, calmodulin, and the Src family of kinases.²⁴ The SNARE (soluble N-ethylmaleimide-sensitive-fusion-protein attachment protein receptor) proteins are thought to assist in fusion by engaging cognate receptors on the target membrane and approximating the two membranes. Antibodies to the SNARE 5, syntaxin 6 and SNAP-23, inhibited exocytosis of azurophilic and specific granules, respectively.²⁴

Neutrophil Granules and Secretory Vesicles. There are two arms to the microbicidal capacity of the neutrophil: an oxygen-dependent pathway, or “respiratory burst,” that generates toxic oxygen derivatives and an oxygen-independent

BOX A

pathway that utilizes toxic proteinases.²⁵ These two components are compartmentalized into four distinct granules or vesicles that also contain adhesion molecules and important inflammatory mediators (Table 6.2).²⁶ They are mobilized in a hierarchical fashion in response to gradual elevations in the intracellular calcium level, which parallels their respective contents and the current needs of the cell.²⁷

Primary, or azurophil (affinity for the dye azure A), granules target the destruction of phagocytosed organisms (Table 6.2). The myeloperoxidase (MPO) within these granules generates hypochlorous acid from products generated by nicotinamide adenine dinucleotide phosphate (NADPH) oxidase and also imparts the characteristic greenish color of pus.^{9,27} Other

major constituents include α -defensins, cytotoxic proteins that scaffold into transmembrane pores within the microbial cell wall and perturb the maintenance of vital transmembrane gradients, and bactericidal/permeability-increasing protein (BPI), which binds to gram-negative organisms and induces rearrangement of membrane lipids and inhibits growth.²⁷⁻³⁰ Elastase cleaves constituents of the extracellular matrix, including proteoglycans, collagen (types I, III, IV), and fibronectin and, of course, elastin.³¹ Azurocidin is chemotactic for monocytes and stimulates LPS-induced release of IL-6 and TNF- α from monocytes.^{4,27}

The contents of specific granules, which are rich in antimicrobial substances, are released extracellularly (Table 6.2).²⁶

BPI, bactericidal/permeability-increasing protein; CD, cluster of differentiation; CR1, complement component C3b; DAG, diacylglycerol; fMLP, N-formylmethionyl-leucyl-phenylalanine; iNOS, inducible nitric oxide synthase; R, receptor; TNF, tumor necrosis factor; uPA, urokinase-type plasminogen activator. Modified from Faurschou M, Borregaard N. Neutrophil granules and secretory vesicles in inflammation. *Microbes Infect* 2003;5:1317–1327.

Lactoferrin, by sequestering iron, retards bacterial growth and can bind bacterial cell membranes and induce irreversible membrane damage and lysis.²⁷ Phospholipase A₂ (PLA₂) participates in the degradation of bacterial membrane phospholipids. Lysozyme, present in all granules, is a cationic antimicrobial peptide that cleaves peptidoglycan polymers of bacterial cell walls. Other extracellular matrix-degrading enzymes include gelatinase and collagenase.²⁷ These granules also possess receptors for a variety of extracellular matrix proteins and cell surface ligands, such as the β_2 -integrin Mac-1 that mediates firm adhesion to the endothelium. In addition to the mechanical function of cellular anchorage, engagement of these receptors with their respective counterligands induces phenotypic alterations such as degranulation and enhanced reactive oxygen species production.^{4,27}

Gelatinase granules contain an eclectic array of mediators that contribute to many aspects of inflammation (Table 6.2).

They contain matrix metalloproteases, zymogens that upon proteolytic activation degrade the interstitial matrix including collagens, fibronectin, proteoglycans, and laminin; this may facilitate neutrophil extravasation and migration. They are a source of cell surface adhesion molecules.^{4,27,30}

Secretory vesicles contain many of the cell surface adhesion molecules operant during and essential for leukocyte recruitment. Their membranes are dense with the β_2 integrins LFA and Mac-1, the complement receptor 1 (CR1), the LPS receptor CD14, and the Fc γ RIII. Through fusion with the plasma membrane, the cell surface is enriched with these receptors, which facilitates firm neutrophil-endothelial engagement and the capacity to respond to a variety of stimuli.^{4,27} Not surprisingly, because of the essential nature of leukocyte recruitment, secretory vesicles possess the lowest threshold for release, followed by gelatinase, specific, and azurophil granules (Table 6.2).²⁷

TABLE 6.3**MAJOR ROS AND THEIR METABOLISM**

■ ROS MOLECULE	■ MAIN SOURCES	■ ENZYMATIC DEFENSE SYSTEMS	■ PRODUCTS
Superoxide ($O_2^{\bullet-}$)	Leakage from electron transport chain Activated phagocytes Xanthine oxidase Flavoenzymes	Superoxide dismutase Superoxide reductase	$H_2O_2 + O_2$ H_2O_2
Hydrogen peroxide (H_2O_2)	From $O_2^{\bullet-}$ via superoxide dismutase NADPH oxidase Glucose oxidase Xanthine oxidase	Glutathione peroxidase Catalase Peroxiredoxins	$H_2O + GSSG$ $H_2O + O_2$ H_2O
Hydroxyl radical ($O_2^{\bullet-}$)	From $O_2^{\bullet-}$ and H_2O_2 via transition metals		
Nitric oxide (NO)	Nitric oxide synthases	Glutathione/TrxR	GSNO

NADPH, nicotinamide adenine dinucleotide phosphate; ROS, reactive oxygen species; TrxR, thioredoxin.
 Modified from Nordberg J, Arner E. Reactive oxygen species, antioxidants, and the mammalian thioredoxin system. *Free Radic Biol Med* 2001;31:1287-1312.

Oxidative Burst and Oxidant Metabolites. The generation of toxic oxygen metabolites or reactive oxygen species (ROS) is the cardinal characteristic of the neutrophil, but may also be produced by the monocyte/macrophage. Their essential antimicrobial properties are equally destructive to host tissues and implicated in the pathophysiology of many inflammatory disorders (Table 6.3). Counterintuitive to their role in cell destruction, recent evidence also supports a role of ROS in intracellular signal transduction.³²

A free radical is any species possessing one or more unpaired electrons; the valence is irrelevant. They are categorized under the broader term ROS, which encompasses all molecules capable of radical formation. Despite a very brief existence (10^{-11} to 10^{-6} seconds), extensive damage may occur through the induction of free radical chain reactions. Species operant during both physiologic and pathophysiologic inflammation include the following: the superoxide anion ($O_2^{\bullet-}$), the hydroxyl radical ($\bullet OH$), hydrogen peroxide (H_2O_2), and singlet oxygen, as well as the reactive nitrogen intermediates nitric oxide (NO) and peroxynitrite ($ONOO^-$) (Table 6.3). In addition to their antimicrobial properties, ROS may modulate the immune response by activating inflammatory cells and inducing proinflammatory cytokine secretion.^{33,34}

2 Implicit with the capacity for pathogen elimination, however, is the potential for destruction of host tissues. Hence, numerous regulatory mechanisms provide temporal and spatial control of the ROS production. The NADPH oxidase complex itself exists in a disassembled state, and only upon cell activation and the need for ROS production are the subunits approximated and enzymatic function restored.³⁵ In addition, high plasma and tissue concentrations of proteinase inhibitors provide continuous surveillance and systemic control. However, such regulation is incomplete as evidenced by such diseases as rheumatoid arthritis, chronic obstructive pulmonary disease, and autoimmune vasculitis, which are the consequence of damage due to neutrophil-derived products.³⁵

NADPH oxidase is a heteromeric complex composed of six subunits: flavocytochrome b558, the electron transporting apparatus, which is subdivided into Gp91(phox) and p22(phox); the cytosolic complex p40(phox), p47(phox), and p67(phox); and the oxidase factor rac-2 (Fig. 6.2).³⁵ Microorganisms or high concentrations of chemoattractants bind to cell surface receptors and initiate oxidase activation, heralded by phosphorylation of p47(phox). Cytochrome b558 (Gp91 and p22), which exists within the plasmalemma and the

membranes of specific granules and secretory vesicles, is recruited by phagocytosis and granule fusion. Phosphorylation of p47(phox) induces a conformation change that enables its incorporation within the membrane, wherein it facilitates the translocation of rac2 and p67(phox), and stabilizes the association of this cytosolic complex with cytochrome b558, thereby rendering the complex functional.³⁵

At the redox center of the oxidase, an electron is transferred from NADPH to oxygen, thereby generating superoxide³⁶:

FIGURE 6.2. Reduced nicotinamide adenine dinucleotide phosphate (NADPH) oxidase assembly. In the resting neutrophil, the cytochrome subunits Gp91 and p22 are tightly bound in the membrane. p47(phox), p67(phox), and rac-s complex are in the cytosol. On activation, GDI releases rac-2, and p47(phox) becomes phosphorylated. This causes translocation of rac-2, p47(phox), and p67(phox) to the membrane and complex formation with the cytochrome components, thereby completing the assembly of the active oxidase. (Redrawn from Burg ND, Pillinger MH. *Clin Immunol* 2001;1:7-17.)

Other mechanisms of superoxide production include uncoupling of the xanthine dehydrogenase system, uncoupling of mitochondrial and endoplasmic reticulum electron transport chains, and nonenzymatic reactions such as autooxidation of hemoglobin.^{37,38}

Superoxide is relatively weak and of low bactericidal potency. However, its membrane permeability and role as a reactant in reactions yielding highly toxic products confers upon it a high potential for cellular and tissue damage.³⁶

Superoxide can spontaneously or enzymatically (superoxide dismutase) dismutate into hydrogen peroxide^{35,36}:

It can also be converted to the more potent hydroxyl radical through the metal-catalyzed Haber-Weiss reaction^{35,36}:

or through the Fenton equation^{35,36}:

Under physiologic conditions, lactoferrin found in neutrophil-specific granules provides the iron catalyst for the Haber-Weiss reaction. In the Fenton reaction, superoxide or other biologic reducing agents such as lactate or ascorbate donate electrons to generate the ferrous ions required to react with hydrogen peroxide to produce the hydroxyl radical.^{35,36,39}

The hydroxyl anion is highly reactive and induces DNA strand breaks and base hydroxylations leading to adenosine triphosphate (ATP) depletion and gene mutations. It can attack lipid side chains of membrane phospholipids to form hydrogen peroxide and lipid hydroperoxides in a process called lipid peroxidation. These products can disrupt membrane function, serve as substrates for the production of cytotoxic aldehydes, or uncouple calcium-ATPase and increase cytosolic calcium concentration. Recent data also support a mechanism by which oxidation of critical sulfhydryl residues on the ryanodine receptors induce an “open” configuration and a leak of intracellular endoplasmic reticulum (ER) calcium into the cytosol.⁴⁰ This elevation of cytosolic calcium activates calcium-dependent proteases and phospholipases that propagate cellular damage.³⁹

Superoxide can react with nitric oxide to produce peroxynitrite (ONOO^-) and hydroxyl radical^{36,41}:

The hemoprotein MPO yields the potentially bactericidal hypochlorous acid (HOCl) from the reactants chloride and H_2O_2 . HOCl oxidizes amino acids, nucleotides, and hemoproteins; can activate neutrophil collagenases and permit unabated elastase injury by inhibiting α_1 -antitrypsin; and contributes to hydroxyl radical and singlet oxygen production.^{33,39,42} Though short-lived, subsequent reactions with secondary amines generate secondary chloramines, which are equally toxic but much more stable. These metabolites can oxidize similar cellular components. They can combine with halide anions to generate toxic free halides or with taurine chloramines, which induces membrane attack complex (MAC) complement formation.^{33,39,42}

In light of the pivotal role of MPO during inflammation and pathogen elimination, it is surprising that MPO deficiency is both common and relatively benign. Though MPO-deficient neutrophils show early depressed bacterial killing, bactericidal function normalizes within 60 minutes.⁴³ It is hypothesized that though bacterial killing is impaired, post-phagocytosis oxidase-dependent neutrophil apoptosis is normal, resulting in appropriate regulation of the inflammatory response.⁴³

Singlet oxygen, a highly reactive and extremely short-lived species, is formed by an input of energy to O_2 that reverses the

spin direction of one of the outermost unpaired electrons away from a parallel spin. It is produced during reactions of the MPO- H_2O_2 -halide system and is a potential product of superoxide dismutation and the Haber-Weiss reaction. It is highly electrophilic, reacting with compounds containing electron-rich double bonds, and may react with membrane lipids to produce peroxides.³⁹

The destructive potential of these ROS for both host and pathogen necessitates a mechanism of continuous tight spatial and temporal regulation. The oxidase complex itself exists spatially disaggregated; only upon cellular activation are its constituents assembled and enzymatic function restored (Fig. 6.2).^{35,43} As elegant as is the mechanism by which to control ROS production, so too are the measures employed to eliminate these products when they are no longer needed. Superoxide, the proximal reactant necessary for many of the ROS-generating reactions, is removed by both spontaneous and enzymatic (superoxide dismutase) dismutation to H_2O_2 (Fig. 6.3). H_2O_2 is subsequently reduced to oxygen and water by catalase.^{36,39} In the extracellular environment, this function is performed by glutathione (GSH) peroxidase, a selenium-dependent enzyme that reduces H_2O_2 while oxidizing reduced GSH to its oxidized form. There is evidence that increasing GSH concentrations in monocytes and macrophages blocks ROS-mediated activation of nuclear factor (NF)- κB and subsequent proinflammatory cytokine production.³⁹ The utilization of N-acetylcysteine, a reducing agent that restores GSH, reduces hepatocellular injury in an animal model of warm liver ischemia/reperfusion.³² It has also been shown to reduce contrast-induced nephropathy in patients undergoing imaging procedures requiring the use of iodinated contrast.⁴⁴ Mechanisms of preventing hydroxyl radical-induced tissue damage include the binding of transition metal ions by albumin, ceruloplasmin, haptoglobin, lactoferrin, and transferrin.^{33,36,39} Taurine is a scavenger for HOCl. Other antioxidants that may assist in controlling the reaction include vitamins E (tocopherol) and C. Vitamin C has many antioxidant properties, including the ability to regenerate α -tocopherol. It can prevent activation of neutrophil-derived collagenase and is a powerful scavenger of HOCl, superoxide, singlet oxygen, and hydroxyl radicals. Carotenoids have long double bonds to attract and sequester free radicals. Uric acid is a powerful scavenger of water-soluble radicals such as HOCl and singlet oxygen. It can

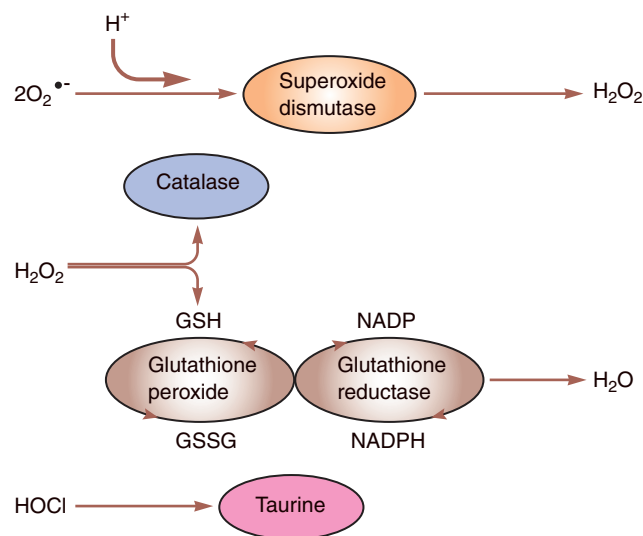

FIGURE 6.3. Scavengers of reactive oxygen species (ROS). (Redrawn from Klebanoff SJ. In: Gallin JI, Snyderman R, eds. *Inflammation: Basic Principles and Clinical Correlates*, 3rd ed. Philadelphia, PA: Lippincott Williams & Wilkins; 1999:723.)

also bind copper and iron ions to suppress hydroxyl radical formation. Stress proteins or heat-shock proteins are induced by oxygen radicals and ischemia and may play a role in defense. Furthermore, heme oxygenase-1 (HO-1) catalyzes the cleavage of heme to biliverdin, which is subsequently converted to bilirubin, an efficient free radical scavenger.^{33,36,39}

All of the aforementioned participants of the NADPH oxidase are vital for health, as evidenced by those who suffer from chronic granulomatous disease.^{35,43} These patients have deficient superoxide production and experience ineffective inflammatory reactions to infection. They commonly suffer from repeated bacterial infections (pneumonia, cutaneous abscesses and hepatic and perihepatic abscess, and osteomyelitis) by organisms that are catalase positive (*Staphylococcus aureus*).

Organisms that produce large amounts of peroxide are less of a threat as the neutrophils can utilize bacterial peroxide to produce toxic metabolites. The use of prophylactic antibiotics and IFN- γ has reduced the frequency of serious infections in this patient population.^{35,43}

Regulation of Inflammation. In addition to the previously described mechanisms for controlling the inflammatory response of neutrophils, there is substantial evidence supporting the role of apoptosis in resolving the inflammatory response (Box B).⁴⁵ Within 90 minutes of phagocytosis, over 250 genes are induced, of which more than 30 encode proteins integral to at least three distinct apoptotic pathways.⁴⁵ These observations suggest that the mechanism inducing apoptosis is

Apoptosis. Apoptosis is an integral component in the regulatory mechanisms that limit and resolve inflammation. Unlike cell necrosis, which is characterized by loss of membrane integrity, cellular edema and lysis, and release of intracellular products that incite an inflammatory reaction, apoptosis is a physiologic process of programmed cell death, characterized by DNA fragmentation and plasma membrane blebbing, with the compartmentalization of cytoplasmic and membrane particles into apoptotic bodies consisting of cytoplasmic and membrane fragments. Cytoplasmic contents are not released and consequently, an inflammatory response is not induced. Neutrophils are programmed to undergo apoptosis constitutively, and the signal transduction pathways culminating in apoptosis are activated early in acute inflammation. Subsequent neutrophil apoptotic particles are phagocytosed by resident macrophages. This is the preferred mechanism for clearing neutrophils from inflammatory foci, and has also been implicated in the clearance of eosinophils, monocytes, and lymphocytes.

Apoptosis plays a prominent role in the immune system. Most developing T cells undergo apoptosis during the selection process in the thymus. Termination of the cellular immune response also involves cytokine-induced apoptosis. Apoptosis can be used by lymphocytes as a means of effecting death in other cells. CTL kill target cells by inducing apoptosis via a Fas-induced pathway and a perforin- and granzyme-mediated pathway. Increased apoptosis has been observed in lymphoid tissues of patients dying of sepsis, suggesting that excessive lymphocyte apoptosis may contribute to fatal sepsis.

Inducers of apoptosis include oxidant stress, radiation, viral infection, trauma, and cytokines. Many of the pathologic agents that induce apoptosis at low concentrations can cause necrosis at higher concentrations. Apoptogenic stimuli activate the apoptotic pathway through both receptor-dependent and independent pathways. The sphingomyelin breakdown product, ceramide, is implicated as a transducer of apoptosis. DNA damage secondary to radiation or oxygen radical formation results in the accumulation of the tumor suppressor gene p53. p53 promotes non-receptor-mediated modulation of apoptosis.

Receptor-mediated pathways involve the “death receptors” that belong to the TNF receptor superfamily. Ligands shown to induce apoptosis include FasL, TNF, TNF-related apoptosis-inducing ligand (TRAIL), nerve growth factor, and CD40L. The best-characterized death receptors are Fas bound by FasL and TNFR1 bound by TNF and lymphotoxin α . Although primarily produced by macrophages, TNF is expressed on many cell types, whereas FasL is restricted to the surfaces of CTL, macrophages, and neutrophils. TNF and FasL also differ in that FasL directly activates a cell death pathway, whereas TNF does so indirectly and concurrently stimulates pathways that inhibit apoptosis. Independent and divergent proinflammatory signaling pathways by TNF lead to the induction of NF κ B, an inhibitor of apoptosis. The mechanism by which several cytokines, including IL-1, IL-6, and GM-CSF, inhibit apoptosis is through induction of NF κ B and apoptosis is one of many factors that ultimately determine the cell’s fate.

Ligation of death receptors recruits “death domain” containing adaptor proteins that interact with the receptor’s intracellular death domain. This interaction initiates the enzyme cascade responsible for apoptosis effector mechanisms, the caspases. All signaling pathways converge on the activation of cysteine proteases related to IL-1 β converting enzyme called caspases. Caspases propagate apoptotic signaling by cleaving/activating other caspases, and eventually execute terminal events in apoptosis by cleaving specific target proteins. Caspases 8 and 10 activate apoptosis signaling by linking Fas-associated death domain protein (FADD) with the caspase cascades. Caspases 3 and 7 are the executor molecules in the nucleus that cleave death substrates, including nuclear structural proteins, protein kinases, and proteins involved in cell cycle regulation or DNA fragmentation. Cytochrome C release from mitochondria is a key component in the activation of caspases. Cytochrome C release, and therefore apoptosis, is inhibited by Bcl-2, the primary death protection protein that belongs to the Bcl family of proapoptotic and antiapoptotic proteins involved in the regulation of apoptosis.

initiated quite proximal in the inflammatory cascade, in fact, just subsequent to phagocytosis. The timely execution of a controlled cell death program in human PMNs is essential for preventing damage to healthy tissues and for the resolution of infection. Furthermore, evidence suggests that the phenotype of other immune cells, including monocytes and macrophages, is altered after encountering and phagocytosis of apoptotic neutrophils. During some processes such as infection or trauma, neutrophil apoptosis may be delayed, which might contribute to a failure to resolve inflammation.

The inflammatory capacity of neutrophils is also transcriptionally regulated. Genes encoding proinflammatory mediators or signal transduction molecules such as receptors for IL-8, IL-10, and IL-13 are downregulated early after activation and decrease rapidly after the initiation of apoptosis.⁴⁵ In addition, regulating oxidative stress and ROS achieve high priority as the genes involved in glutathione and thioredoxin metabolism and heme catabolism are upregulated as is the production of reduced glutathione.⁴⁵ Hence, activation-induced apoptosis in neutrophils stimulates self-directed regulation, an event that likely facilitates removal of neutrophils by macrophages. As aforementioned, removal of apoptotic neutrophils by activated macrophages also appears to serve a role in modifying their function and halting the inflammatory response.

Mononuclear Phagocytes

Monocytes circulate for about 1 to 2 days; thereafter, they constitutively hone to a particular tissue to differentiate into macrophages possessing a phenotype specific to the resident tissue (dendritic cells, Kupffer cells) (Table 6.1).^{4,46,47} Resident macrophages are typically found at interfaces with blood (liver and spleen) and with lymph, where they can readily detect, ingest, and destroy invading organisms.³⁹ Mononuclear cells function as antigen-presenting cells in T-cell-mediated adaptive immune responses, presenting antigen in the appropriate context to effector T cells. They provide service integral to both innate and adaptive immune responses. Evidence also supports their role in providing an “alarm” both locally and systemically through the release of intracellular proteins (i.e., high-mobility group box 1 protein [HMGB1]) expressing damage-associated molecular patterns (DAMPs) that can function as a danger signal (see later).

Recruitment

Monocytes are recruited and emigrate to foci of inflammation utilizing similar mechanisms of adhesion and diapedesis as described for neutrophils (Fig. 6.1). PAF; C5a; the CC chemokines, regulated on activation, normally T-cell expressed and secreted (RANTES); macrophage inflammatory protein (MIP)-1 α ; and chemokines of the membrane cofactor protein (MCP) family are potent monocyte-macrophage chemotaxins.^{48,49} The selectin family of adhesion receptors mediates the initial tethering of monocytes to endothelial cells.¹⁸ Firm adhesion to the endothelium involves the interactions of β_1 and β_2 integrins on monocytes with the endothelial adhesion molecules ICAM-1 and VCAM-1.¹⁸

Phagocytosis. Phagocytosis involves both the IgG receptor (Fc γ R) and the receptor for the complement factor C3b. Terminal sugar patterns on microbial surfaces also allow recognition by macrophages for nonspecific phagocytosis.²² However, phagosomal maturation differs from that which occurs in the neutrophil in that monocytes and macrophages have an endocytic pathway targeting the phagosome to a lysosome.²⁴ After endocytosis of a receptor–ligand complex, the contents of a vesicle are targeted to an early endosome, the ligand and

receptor dissociate, and the receptor is recycled to the cell surface.²⁴ This early endosome undergoes a series of maturation steps in which it is acidified (pH 5.5 to 6.0). This acidification is requisite for optimal protease and hydrolase activity involved in pathogen killing. It may also be integral for phagosome maturation as titrating the acidity inhibits phagosome–lysosome fusion.²⁴ Ultimately, the endosome fuses with a lysosome, which is characterized by its extreme acidity (pH <5.0) and elevated concentration of proteases.²⁴ Lysosomes are the terminal destination of phagocytosed material to be degraded.

After fusion, MPO released into phagosomes can react with hydrogen and halides to yield toxic hypohalous acids, superoxide anion, hydrogen peroxide, and hydroxyl radical (Table 6.3). Macrophages may also use peroxidase generated by adjacent neutrophils, eosinophils, and monocytes and acquired through endocytosis to generate these ROS. In addition to supporting the inflammatory response, macrophages also play an important immunoregulatory role in inflammation by scavenging apoptotic neutrophils at sites of inflammation.³⁹

Activation. IFN- γ derived primarily from T cells is the primary activator of macrophages.^{4,47,50} Optimal macrophage activation requires both interferon IFN- γ and a sensitizing agent, both of which can be provided by activated T lymphocytes. CD40 ligand on T cells can bind CD40 on macrophages to sensitize the cell. Alternatively, membrane-associated TNF- α or lymphotoxin from lymphocytes can activate macrophage TNF- α synthesis and thereby sensitize the macrophage to IFN- γ .³⁹ IL-10 promotes monocyte maturation and macrophage differentiation.⁵¹ Other activators include GM-CSF, TNF- α , IL-1, and LPS.

Activated monocytes and macrophages can produce approximately 100 different products, including GM-CSF, macrophage colony-stimulating factor (M-CSF), G-CSF, IL-1, TNF- α , and NO (Table 6.4).^{39,52} Mononuclear phagocytes are important sources of chemoattractants such as IL-8, PAF, and LTB $_4$ that recruit other neutrophils and leukocytes. Their release of HMGB1 and other DAMP molecules serves as a danger signal to other immune cells in the local environment. However, systemic release of HMGB1 may be causally related to mortality in such inflammatory states as sepsis and trauma.^{53,54} The respiratory burst and subsequent production of toxic ROS mirrors that of neutrophils.

Antigen Presentation. T cells recognize only those antigens associated with surface major histocompatibility complex (MHC) molecules. MHC class I molecules are expressed on all nucleated cells, whereas MHC class II molecules are restricted to antigen-presenting cells (APCs). After phagocytosing pathogen, mononuclear cells process and display antigen to T cells, and in doing so, initiate the development of the adaptive response. There is evidence that the heat-shock protein receptor CD91 may also participate in this process (vide infra). This processed antigen is presented in the context of MHC molecules on the APC surface that are specifically recognized by T-cell receptors and essential for T-cell activation. CD4 $^+$ T cells, or helper T cells (T $_H$), recognize antigen coexpressed with MHC class II molecules and induce B-cell differentiation into either memory or antigen-specific antibody-producing plasma cells. These T $_H$ cells can also induce macrophage production of NO, ROS, and other inflammatory mediators. CD8 $^+$ cytotoxic T lymphocytes (CTLs) recognize antigen in the context of MHC class I molecules and induce target cell lysis; they destroy host cells infected with intracellular pathogens or cells of malignant potential.⁵⁵ Activated mononuclear phagocytes release IL-12, a potent stimulus for T $_H$ cells and the production of inflammatory cytokines, and elaborate IL-15, the function of which mirrors that of IL-2.^{56,57}

The three professional APCs are dendritic cells (DCs), macrophages, and B cells. Dendritic cells are a specialized APC, which process and present antigen to naïve T cells.

TABLE 6.4**MONOCYTE/MACROPHAGE PRODUCTS**

■ PRODUCT	■ FUNCTIONS
Enzymes	
Lysozyme	Antimicrobial
Urokinase	Plasminogen activation and fibrinolysis
Collagenase	Connective tissue degradation
ACE	Vasopressor
Cytokines	Multiple
IL-1	Multiple
TNF- α	Antiviral, immune modulation
Interferon α/β	Acute-phase response
IL-6	Anti-inflammatory
IL-10	Stimulate IFN- γ production
IL-12, IL-18	Neutrophil chemoattraction
IL-8	Fibroblast growth
FGF	Granulocyte, macrophage differentiation
GM-CSF	Chemoattractant
MIP-1 α/β	Monocyte recruitment
MCP-1	Monocyte/T _H cell recruitment
RANTES	Opsonization, complement activation
Complement proteins	Coagulation
Coagulation factors	Localization, migration
Adhesion, matrix molecules	Iron transport
Fibronectin, proteoglycan	Vitamin transport
Transport proteins	Inflammation
Transferring	Inflammation
B ₁₂ -binding protein	Platelet activation
Bioactive lipids	Antimicrobial
Cyclooxygenase	Antimicrobial
Lipo-oxygenase	Antibacterial
PAF	
Reactive oxygen intermediates	
Superoxide, hydrogen peroxide, oxygen singlet	
Reactive nitrogen intermediates	
NO, nitrates, nitrites	
Defensins	

ACE, angiotensin-converting enzyme; FGF, fibroblast growth factor; GM-CSF, granulocyte/macrophage colony-stimulating factor; IL, interleukin; MCP, membrane cofactor protein; MIP, macrophage inflammatory protein; NO, nitric oxide; PAF, platelet-activating factor; RANTES, regulated on activation, normally T-cell expressed and secreted; TNF, tumor necrosis factor.

Modified from Gordon S. Development and distribution of mononuclear phagocytes: relevance to inflammation. In: Gallin JL, Snyderman R, eds. *Inflammation: Basic Principles and Clinical Correlates*, 3rd ed. Philadelphia, PA: Lippincott Williams & Wilkins; 1999.

Monocytes stimulated with GM-CSF and IL-4 or IL-13 differentiate toward DCs. Maturation of the DC requires TNF- α or LPS stimulation.³⁹ Epidermal Langerhans cells, after encountering antigen, migrate through the lymphoid organs and differentiate into mature DCs and acquire the capacity to provide the costimulatory signal. DCs are particularly effective at presenting viral antigen. They present antigen in the context of both MHC I and MHC II and thereby induce both a T_H1 and T_H2 response, respectively. DCs can also present antigens derived from apoptotic cells in the context of MHC class I.^{58–60}

Macrophages present antigenic peptides from ingested pathogens that persist in the phagosomes. These peptides, usually of bacterial origin, are expressed in conjunction with MHC class II molecules. B cells, by contrast, bind specific soluble molecules (insect toxins, venom, and allergens) via immunoglobulin. This is endocytosed, processed, and presented on surface MHC II.^{39,60–62}

Lymphocytes

B, T, and natural killer (NK) cells comprise this lineage of inflammatory cells (Table 6.1). B and T cells are central to the adaptive immune response, whereas NK cells lack antigen specificity and primarily function during innate immune response. NK cells are the first line of defense against many viral infections; the loss of surface expression of MHC class I molecules on virus-infected cells serves as a target for NK cells.^{39,63} Alternatively, NK cells bind cell-bound antibody and participate in antibody-dependent cell cytotoxicity. Cells targeted by either mechanism are induced to undergo cell death.

B Lymphocytes. B cells are of bone marrow origin, yet attain full maturation within extramedullary sites such as lymph nodes, the spleen, and the mucosal lymph nodules of the tonsils and Peyer patches. With activation, B cells differentiate into antibody-producing plasma cells, which through the elaboration of antibody, aid the neutralization of viruses and bacterial toxins and facilitate opsonization for phagocytosis and complement activation.⁴ Activation requires antigen binding to cell surface receptors and stimulation by T_H cell–derived cytokines; they do not need the assistance of APCs. Polyclonal B-cell activation can occur in a T-cell–independent mechanism if the antigen has a large repeating polymeric sequence.^{39,64}

T Lymphocytes. Development of T lymphocytes begins within the marrow and is completed in the thymus. The final population profile is determined by apoptotic processes of both positive and negative selection.⁶⁵ Any protein or antigen of host origin is presented by APCs, and thymocytes reactive to these self-proteins are deleted.⁶⁶ Alternatively, expansion of cell lines recognizing foreign, or rather non-self, antigen, occurs through positive selection. IL-7 provides the stimulation for proliferation and differentiation of developing T cells. Ultimately, two lines of mature cells, CD4⁺ and CD8⁺, will develop.⁶⁷

Lymphocytes, the smallest of the leukocytes, constitute approximately 20% of circulating leukocytes.⁴ Most circulating lymphocytes are T cells, and 60% of those are CD4⁺, a marker of a T_H phenotype. The other 40% are CD8⁺, called cytotoxic T cells, T_C. The normal ratio of CD4⁺ to CD8⁺ is 2:1.⁴ Lymphocytes continuously recirculate through the lymph nodes, spleen, lymphatics, lymph nodules, and blood, providing continuous surveillance. Encounter with a particular antigen initiates activation toward an effector T cell. Activation of a T cell requires its specific antigen binding plus a costimulatory signal provided by the interaction between costimulatory molecules on the APC and their cognate receptors on the T cell.³⁹

Naïve T cells circulate continuously between blood and lymphoid organs, making contact with many APCs and the epitopes of the antigens they express.⁶⁸ Initially, lymphocytes enter the cortical region of lymph nodes by migrating across

the high endothelial venules, a process mediated by the selectin family of receptors. L-selectin, which is found constitutively on all lymphocytes, binds sialyl Lewis x carbohydrate on the endothelium.³⁹ For example, L-selectin on lymphocytes binds GlyCAM-1 on the high endothelial venules in lymph nodes. In mucosal tissues, endothelial MADCAM-1 guides L-selectin-mediated emigration. Migration across the endothelium requires integrins, in particular LFA-1.⁶⁹ Binding of LFA-1 to ICAM-1 and ICAM-2 on endothelial cells facilitates migration. Most lymphocytes are carried back to the blood by the efferent lymphatics. If a T lymphocyte recognizes its specific antigen on the surface of an APC, it remains for several days, then returns to the blood as an armed effector T cell.³⁹

Adhesion molecules mediate many of the transient interactions between T cells and APCs required for the T cell to sample each antigen it encounters. Lymphocyte LFA-1 can bind the APC in a loose, reversible fashion by any of the ICAM molecules on APCs. If a match between T cell and antigen is found, conformational changes in LFA-1 greatly increase its affinity for ICAM-1 and ICAM-2 to stabilize the interaction. The T cell can then proliferate and differentiate into an effector cell. Effector T cells lose surface expression of L-selectin and no longer circulate through lymphoid tissue. Instead they express VLA-4, an integrin, which binds vascular endothelium at sites of infection. Effector T cells have increased LFA-1 and CD2 adhesion molecule expression that facilitate tight binding to the target cell.^{70,71}

Antigen binding in the appropriate context provides the signal for clonal expansion and differentiation of T cells into effector and memory lymphocytes. The appropriate contact is composed of antigen complexed with MHC class II molecules on APCs, costimulators, and cytokines produced by the APCs and by the T cells themselves. This first encounter of naïve T cells with antigen is the primary immune response, which serves to induce the formation of effector and memory T cells. These activated T cells hone to peripheral tissues, where, upon reexposure to the antigen for which they are specific, they activate macrophages to eliminate phagocytosed microbes and induce B-cell differentiation and antigen-specific secretion. The CD8⁺ CTLs kill infected host cells and tumor cells that display class I MHC-associated antigen. Naïve T cells require activation by dendritic cells, whereas effector T cells can respond to antigens presented by a wider variety of APCs, such as macrophages and B lymphocytes. Not surprisingly, differentiated effector and memory T cells possess lower thresholds for costimulation and require lower antigen concentration for activation than naïve T cells.

In general, antigen presented on MHC II molecules is the prototypical stimulus for CD4⁺ T-cell activation and the subsequent production of a variety of cytokine mediators, including IL-2, which stimulate further expansion and activation. However, the circumstances under which this activation occurs may dictate disparate paths of differentiation, producing T-cell subsets with distinct cytokine profiles and effector functions. These differing phenotypes have been utilized to characterize two distinct subsets: T_H1 and T_H2.^{56,57,72} IL-12 derived from phagocytes infected with intracellular pathogen provides the necessary signal for T_H1 differentiation.³⁹ IL-12 also stimulates production of IFN- γ , the principal macrophage activator, by NK cells and CD4⁺ lymphocytes. Interferons stimulate T_H1 development by augmenting phagocytic IL-12 production and by maintaining IL-12 receptor expression on CD4⁺ T cells. The principal effector action of T_H1 cells is the activation of macrophages through the production of IFN- γ , GM-CSF, TNF- α , CD40L, and FasL.^{39,56,57,72} They regulate production of opsonizing and complement fixing antibodies and are effectors of phagocyte-dependent responses. This inflammatory response is also referred to as cell-mediated immunity or delayed-type hypersensitivity, provides one major arm of the adaptive immune response, and is mediated by CD4⁺ and CD8⁺ lymphocytes and macrophages.

4 The principal stimulus for T_H2 differentiation is IL-4, which is derived from T cells, mast cells, and basophils.^{56,57,72} These cells are the cellular effectors of humoral immunity and provide the other major arm of the adaptive immune response, which is mediated by T_H2 CD4⁺ cells, B cells, plasma cells, and antibodies. They produce IL-4, IL-5, and CD40L, thereby inducing B-cell activation and antibody production and a host of other proinflammatory and anti-inflammatory cytokines.³⁹ Activation of mast cells and eosinophils by extracellular pathogens is associated with activation of T_H2 cells. T_H2 cells quell the inflammatory response by inhibiting macrophage functions and T_H1 responses; they are considered the anti-inflammatory arm of cell-mediated inflammation. Helper T cells that express both T_H1 and T_H2 patterns of cytokine expression have been called T_H0 cells, and further studies will certainly discern other subsets of T cells.^{4,72}

T-cell activation, differentiation, and expansion are orchestrated by the T cell itself. The responding T cell, in an autocrine fashion, serves as both source and target of a variety of mediators stimulating growth. The principal autocrine growth factor is IL-2, which is induced by signaling regulated by the phosphatase calcineurin (see later).⁷³ IL-15 stimulates the proliferation of CD8⁺ T cells, especially memory cells of the CD8⁺ subset. After antigen exposure, the numbers of T cells specific for that antigen may increase to about 1 in 10 for CD8⁺ and 1 in 1,000 to 10,000 for CD4⁺ cells.⁴

After activation, some proliferating cells will differentiate into effector cells that eliminate antigens and may activate other immune cells. Mature CD4⁺ cells induce the activation of mononuclear phagocytes and B cells. CD8⁺ cells differentiate into CTLs that recognize viral and other intracellular pathogen antigens that are presented in the context of MHC class I molecules and induce target cell death by releasing the cytotoxins perforin and granzymes from cytoplasmic granules. Granzymes are serine proteases that trigger DNA fragmentation and apoptosis. Perforin stimulates cell membrane pore formation, which facilitates granzyme entrance into cells. Apoptosis can also be induced by the binding of Fas ligand on CTL to Fas on the target cell. CTLs also release the cytokines IFN- γ , TNF- α , and CC chemokines. IFN- γ and certain CC chemokines have antiviral properties, and both are potent activators of macrophage function. IL-2 produced by CTL and local helper CD4⁺ lymphocytes expands the CTL, and IL-12 released by APC stimulates CTL activity. As with CD4⁺ cells, early evidence suggests that the population of CD8⁺ cells may be divided into T_C1 and T_C2 cells based on their cytokine profiles and effector functions.^{39,55-57}

Other T cells will mature into long-lived functionally quiescent memory cells. A cell surface rich in adhesion molecules such as integrins and CD44 facilitates rapid and efficient migration to peripheral sites of infection and inflammation upon antigen reexposure.⁴ These cells accumulate over time and in the adult human comprise more than half of the circulating T cells.

Mere antigen exposure is insufficient for activation of naïve T cells; proliferation and differentiation require costimulatory signals provided by molecules on APCs. The best-characterized costimulator pathway involves the T-cell surface molecule CD28 and its counterligand B7-1 and B7-2 expressed on activated APCs.^{4,39} CD28 delivers signals that enhance T-cell survival by increasing expression of the antiapoptotic protein Bcl-X, the production of cytokines such as IL-2 and the IL-2 receptor, and the differentiation of immature T cells. In vitro, purified populations of CD4⁺ cells challenged with antigen by APCs that express B7 proliferate and secrete cytokines, yet not if B7 is absent. The costimulatory signal must come from the same APC that provides the initial signal. DCs are the most potent APCs because they express both classes of MHC molecules and the B7 molecules. Macrophages and B cells must be activated to express the costimulatory molecules. This expression of costimulators is regulated so as to ensure that T-cell activation is temporally and spatially appropriate. For instance, during T-cell activation, engagement of CD40 ligand with

CD40 induces upregulation of B7 costimulators on the APCs. In addition, it increases the secretion of cytokines such as IL-12 that promote T-cell differentiation, and cytokines are secreted that promote T-cell differentiation and activation. A protein called CTLA-4 is homologous to CD28, binds B7-1 and B7-2, and is expressed on activated T cells. Unlike CD28, CTLA-4 functions to terminate T-cell responses and plays a role in self-tolerance. On the basis of many experimental studies of costimulators, antagonists against B7 molecules and CD40L are in clinical trials to prevent the rejection of organ allografts.^{4,39}

The differentiation of naïve CD8⁺ T cells to CTL requires a stronger costimulatory signal. This can be provided by either DCs, as they have the greatest intrinsic costimulatory activity, or by a CD4⁺ helper T lymphocyte. Naïve helper T cells attached to the same APC as the CD8⁺ T cell can be activated to elaborate IL-2. Attached effector T helper cells can stimulate the APC to express more costimulatory molecules. In the case of virulent viruses, cytotoxicity substitutes for CD28 costimulation, and so the typical costimulatory signal is not required for activation. For less virulent viruses, costimulation is necessary for CTL induction.^{39,74} The absence of costimulation results in an unresponsive, or anergic, T cell. Recently this has been shown to be mediated by the serine/threonine kinase calcium/calmodulin-dependent protein kinase (CaMK) II (see later).⁷⁵ Anergic T cells do not produce IL-2 and therefore cannot proliferate and differentiate into effector cells even when presented with antigen at a later time.³⁹

The affinity of most T-cell receptors (TCRs) for peptide-MHC complexes is low, with dissociation constants on the order of 10^{-5} to 10^{-7} and an estimated TCR-antigen interaction of less than 10 seconds. Furthermore, on any APC, fewer than 1,000 of the 10^5 available MHC molecules are likely to be displaying any one peptide at any particular time. Therefore, one APC can engage a small fraction of the 10^4 to 10^5 antigen receptors on a single T cell.⁴ Activation of an individual T cell may require multiple sequential engagements of that cell's antigen receptors by peptide-MHC complexes on APCs. With engagement, there is clustering of membrane receptors, tyrosine phosphorylation of several proteins, and recruitment and activation of adaptor proteins. TCRs are devoid of enzymatic activity and must utilize other signal-transducing proteins.⁴

After TCR-MHC engagement, several membrane surface proteins and intracellular signaling proteins are rapidly recruited, including the TCR complex, CD4 or CD8, receptors for costimulators such as CD28, and enzymes and adaptor proteins.⁴ After TCR clustering, activated tyrosine kinases that are associated with the cytoplasmic domains of CD3 phosphorylate tyrosine residues on both CD3 and TCR (Fig. 6.4). These phosphorylation sites provide docking sites for other tyrosine and protein kinases, such as Lck, an Src family of tyrosine kinase, and ZAP-70, a tyrosine kinase. These kinases become activated with phosphorylation. Activated ZAP-70 phosphorylates several adaptor proteins that subsequently induce a variety of signal transduction cascades. Adaptor proteins contain structural domains that bind other proteins and thereby facilitate the correct spatial orientation to promote the activation of signal transduction pathways. The ras pathway is also activated, which is an early step in the activation of the mitogen-activated protein kinases (MAPKs) that can activate a variety of transcription factors. Ras is a member of a family of guanine nucleotide-binding proteins (guanosine diphosphate [GDP]/guanosine triphosphate [GTP]) that are involved in diverse activation responses in different cell types. This pathway is an amplification process by which few upstream kinases lead to the activation of several downstream kinases. Ultimately, activation of the terminal extracellular regulated kinase (ERK 1/2) leads to the phosphorylation of the protein ELK, which stimulates the transcription of fos, a component of the activation protein 1 (AP-1) transcription factor (Box C). Concomitantly, c-Jun N-terminal kinase (JNK) is activated, which phosphorylates c-Jun, the second component of AP-1. The third member of the MAPK family, p38, is also activated. The activities of the MAPKs are terminated by specific protein tyrosine/threonine phosphatases that are regulated by the MAPKs themselves. Hence, the entire system is self-regulated by a negative feedback system.⁴

Activation of TCR also leads to the induction of phospholipase C (PLC), in particular PLC γ 1 (Fig. 6.4). Phosphorylated PLC γ 1 catalyzes the hydrolysis of phosphatidylinositol 4,5-bisphosphate (PIP₂) into inositol 1,4,5-trisphosphate (IP₃) and diacylglycerol (DAG), and activates enzymes that generate

Transcription Factors. AP, activator protein; CSF, colony-stimulating factor; COX, cyclooxygenase; GF, growth factor; ICAM, intercellular adhesion molecule; IFN, interferon; IL, interleukin; iNOS, inducible nitric oxide synthase; LPS, lipopolysaccharide; MMP, matrix metalloproteinase; MPO, myeloperoxidase; NFAT, nuclear factor of activated T cells; NF κ B, nuclear factor kappa-B; PLA₂, phospholipase A₂; ROS, reactive oxygen species; STAT, signal transducer and activator of transcription; TNF, tumor necrosis factor; UV, ultraviolet; VCAM, vascular cell adhesion molecule. (Modified from Gallin JI, Snyderman R, eds. *Inflammation: basic principles and clinical correlates*, 3rd ed. Philadelphia: Lippincott Williams & Wilkins, 1999)

BOX C

additional active transcription factors. IP₃ increases cytosolic free calcium that leads to a large influx of both intracellular and extracellular calcium with subsequent activation of calcium- and calmodulin-dependent proteins. Calcineurin, a calcium/calmodulin-dependent phosphatase, is integral to T-cell activation via modulation of the activation of the transcription factors nuclear factor of activated T cells (NFAT) and NF- κ B (Box C).^{73,4} These transcription factors are essential for the induction of cytokine transcription, in particular IL-2 production. However, in the absence of costimulation, activation of the CaMK II opposes the actions of calcineurin as described earlier and produces an anergic cell.⁷⁵ DAG activates protein kinase C, which activates additional transcription factors. The role of PKC and calcium in T-cell function is made evident by studies in which pharmacologic activation of PKC and/or elevation of intracellular calcium concentration stimulates T-cell cytokine secretion and proliferation.⁴ Regulation of those kinases operant in T-cell signaling involves protein tyrosine phosphatases. Through dephosphorylation, they modulate TCR signaling. Two phosphatases induced with TCR clustering are SHP-1 and SHP-2.

The ultimate goal of all these signaling transduction pathways is to activate transcription factors that bind to promoter regions and enhance transcription. Three transcription factors that are activated in T cells and appear critical for most T-cell responses are NFAT, AP-1, and NF- κ B (Box C).

A third mechanism of T-cell activation involves lipid antigens such as cell wall protein from intracellular bacteria. These antigens bind CD1, an MHC-related cell surface molecule that presents these antigens to certain subtypes of T cells. A superantigen is an unprocessed bacterial or retroviral product that binds the MHC molecule and the T-cell receptor outside the usual antigen-binding sites. This engagement leads to a polyclonal and non-

specific stimulation of a large proportion of the T-cell population. An overwhelming activation of all arms of the immune system ensues and underlies much of the pathophysiology of toxic shock syndrome. Intravenous immunoglobulin (IVIG), by binding this antigen, is thought to be of therapeutic benefit.

Eosinophils

Eosinophils are marrow-derived granulocytes that share some properties of neutrophils and are involved in the eradication of helminthic infections and allergen reaction (Table 6.1). IL-3, GM-CSF, and IL-5 promote eosinophil differentiation, the induction of effector functions, and survival by inhibiting apoptosis.⁷⁶ They emigrate through inflamed endothelium and upon exiting release inflammatory mediators and toxic agents from cytoplasmic granules. They generate superoxide anion and hydrogen peroxide, though less efficiently than neutrophils. Eosinophils act in conjunction with basophils and mast cells as primary effectors in allergy and inflammation. They express IgE receptors and stimulate histamine release from basophils and mast cells through major basic protein (MBP). They can also regulate basophil and mast cell function by releasing enzymes that inactivate histamine and slow-reacting substance of anaphylaxis (SRS-a). Upon exiting the marrow, their intravascular half-life is but a few hours; thereafter, they enter the mucosa of the lung, gastrointestinal, and genitourinary tracts.^{39,76}

Recruitment and Activation. Eosinophils are primarily recruited to sites of parasitic infection and allergen challenge. Mast cells and macrophages responding to either allergen or parasite secrete cytokines (IL-5, PAF, LTB-4) that upregulate expression of endothelial adhesion molecules. Eosinophils

themselves are more responsive to CC chemokines (MIP-1 α , RANTES, and MCP-3) and the cytokines produced with T_H2 activation. Engagement of the β_1 -integrin VLA₄ of eosinophil with VCAM-1 and fibronectin on the endothelium initiates the process of emigration. IL-4 can activate both the binding and the upregulation of endothelial cell VCAM-1. Diapedesis and tissue infiltration also involve members of the β_2 -integrin family (Mac-1 and LFA) similar to that employed during neutrophil recruitment.^{39,77}

Eosinophils are activated by IL-3, GM-CSF, IL-5, PAF, CC chemokines, and C3a and C5a of complement. IL-5 is a potent activating agent and enhances the ability of eosinophils to release granule contents on FcR cross-linking. A positive feedback cycle ultimately is established, in which recruited eosinophils produce cytokines and chemokines that recruit more eosinophils and other leukocytes.

Granules. Eosinophils possess a compartmentalized armamentarium of toxic substances to assist in the elimination of organisms, in particular helminths. Their specific granules contain GM-CSF and MBP, the latter of which is cytotoxic to parasites and normal cells and is a stimulus for histamine release from mast cells and basophils.⁷⁸ The granule matrix contains eosinophil peroxidase (EPO), eosinophil-derived neurotoxin, lysosomal enzymes, catalase, TNF- α , transforming growth factor- β (TGF- β), and eosinophilic cationic proteins that stimulate formation of transmembrane pores to increase target cellular permeability.⁷⁹ EPO is released extracellularly on target cell surfaces where it generates hydrogen peroxide and hydrogen halides. Approximately 30% of oxygen consumed by stimulated eosinophils is utilized in the formation of halogenating species. Thiocyanate may be the major halide for the EPO-H₂O₂ system.⁸⁰ If ingested by a neighboring phagocyte, EPO can combine with H₂O₂ and halides to form hypohalous acids. EPO also stimulates neutrophil aggregation and adhesion to endothelial cells. Although they express Fc receptors for IgG, IgA, and IgE, they are relatively insensitive to activation by antigen-mediated cross-linking of these receptors. However, they can kill microorganisms by antibody-dependent cell-mediated cytotoxicity (ADCC).^{4,39}

The primary targets of eosinophils are extracellular parasites. The size of these pathogens prohibits phagocytosis, and their integument is relatively resistant to the microbicidal products of neutrophils and macrophages; however, they can be killed by MBP, which is released after cross-linking of Fc-bound IgE coating the parasite. The T_H2 response to parasitic invasion produces IL-4, IL-5, and IL-13. IL-4 stimulates the production of specific IgE antibodies, which opsonize helminths. IL-5 activates eosinophils, which bind to the IgE-coated helminths via Fc receptors. Activated eosinophils then release their granule contents and generate reactive oxygen species and hypohalous acids. EPO also stimulates neutrophil aggregation and adhesion to endothelial cells. The sparse uncompartimental granules contain Charcot-Leyden crystals and have lysophospholipase activity. Finally, eosinophils produce and release lipid mediators such as PAF, prostaglandins, and leukotrienes, which probably contribute to the process of allergic diseases.^{4,81,82}

Basophils and Mast Cells

Basophils and mast cells are central to the development of allergic inflammation and produce cytokines, lipid mediators, vasoactive amines, and proteases that participate in nonallergic inflammatory responses (Table 6.1). Both cells share a common progenitor cell, which diverges early during differentiation. The primary growth factors for basophil development are IL-3 and GM-CSF, whereas stem cell factor is the primary stimulus for mast cell maturation.⁸³ Although basophils and mast cells are distinct cell types, they are often grouped together because of their similarity in granule content, activating stimuli, and effector functions.³⁹

Mature basophils constitute only 0.5% to 1% of the circulating leukocytes, and mast cells primarily reside fixed in connective tissue. Engagement of IgE-bound antigen with the high-affinity IgE antibody receptor, Fc ϵ R, provides the primary stimulus for basophil and mast cell activation and degranulation. In addition, diverse agents such as contrast media, opiates, anaphylatoxins, chemokines, and neuropeptides may serve as activators. Basophils and mast cells elaborate both preformed and newly synthesized inflammatory mediators. The main basophil proteoglycan is chondroitin sulfate A, whereas mast cells contain heparin, chondroitin sulfate, and chondroitin sulfate E and also store neutral proteases.⁸⁴ The lipid mediators LTB₄, LTC₄, and prostaglandin D₂ (PGD₂) are synthesized *de novo* in response to stimulation. The leukotrienes are powerful vasoconstrictors, bronchoconstrictors, and chemoattractants for neutrophils and eosinophils. PGD₂ inhibits platelet aggregation and is chemotactic for neutrophils. Both basophils and mast cells synthesize and secrete histamine. Histamine, or 2-(4-imidazolyl)-ethylamine, is formed by the carboxylation of histidine. It is stored in preformed granules at acid pH as a complex with proteins and proteoglycans. Mast cells carry greater quantities of histamine than do basophils. The classic vasoactive properties of arteriolar dilatation, increased vascular permeability, and bronchoconstriction are mediated by the H₁ receptors. H₂ receptors are involved in modulation of the immune response and stimulating gastric output and mucus secretion. H₃ receptors participate in neuroconduction.^{39,84,85}

Platelets

Though classically considered in the context of hemostasis, platelets are integral to both normal and pathologic inflammation and link the processes of hemostasis, inflammation, and tissue repair. They are activated in a variety of inflammatory conditions, such as rheumatoid arthritis and inflammatory bowel disease, a testimony to their role in inflammation.⁸⁶ Upon activation, they release factors that enhance vascular permeability, chemokines, microbicidal proteins, and mitogens for endothelial cells, smooth muscle cells, and fibroblasts. They assist leukocytes in promoting the inflammatory reaction and killing microbes by providing an adhesive surface to facilitate emigration, by stimulating adhered leukocytes, and by further modulating chemokine synthesis (Table 6.5).^{86,87}

Humans possess about 150 to 400 $\times 10^9$ platelets per liter of blood.⁸⁶ Thrombopoiesis is regulated by thrombopoietin (TPO) as well as a variety of other peptides (IL-3, IL-4, IL-6, IL-7, and IL-11). In fact, human IL-11 is clinically used to stimulate thrombopoiesis in patients undergoing chemotherapy.⁸⁸ After release from the marrow, they circulate with a half-life of approximately 12 days. Interferon- α is inhibitory for megakaryocyte growth, and the elevated levels induced with some viral and inflammatory conditions may explain the relative thrombocytopenia observed in these conditions.^{86,89}

Recruitment and Activation. Platelets are activated and aggregate by exposure to thrombin or activated endothelium. Clot formation triggers the release of vasoactive agents (PGE₂, PGI₂, PGF_{2 α} , and platelet-derived growth factor [PDGF]) and inflammatory mediators. Serotonin, PGE₂, and PAF increase vascular permeability. The adhesion molecule PECAM-1 and the β_3 integrins mediate platelet plug formation, endothelial cell adhesion, and leukocyte emigration. The integrin IIb/IIIa and P-selectin facilitate platelet interactions with other inflammatory cells. The α granules are rich in membrane-bound P-selectin; upon fusion with the cell surface membrane they markedly enhance the cell surface density of this receptor. On stimulation, both receptors are expressed on the platelet surface in an activated state. IIb/IIIa binds various adhesive proteins containing the RGD sequence (i.e., fibrinogen), which serve as a mechanical

link to other platelets, leukocytes, and the endothelium. Possibly the immobilization on the vessel wall of activated platelets with induced P-selectin biochemically and functionally promotes the adhesion of neutrophils to endothelial cells.^{86,89}

Platelets are a primary source of chemoattractants for neutrophils. Neutral proteinases released from stimulated platelets cleave complement factor C5, liberating the chemoattractant C5a. PDGF binds strongly to the extracellular matrix, providing a long-acting source of chemoattractant. Platelet factor 4 (PF4) is a cationic protein that penetrates the vascular wall and is a chemoattractant. Activated platelets also bind monocytes via P-selectin and PSGL-1 and induce the expression and secretion of MCP-1 and IL-8. Thrombospondin released from activated platelets mediates monocyte binding to platelets. Together these substances promote leukocyte margination, activation, and recruitment to the sites of injury.³⁹

Granules. The vasoactive substances and inflammatory mediators of platelets are either stored in cytoplasmic granules or synthesized de novo. A platelet contains about 35 α granules and five dense bodies. The dense granules contain adenosine diphosphate (ADP), ATP, serotonin, and calcium, mediators operant during the initial phase of inflammation. ADP is the principal platelet agonist during platelet aggregation and aug-

ments the oxidative burst of neutrophils. Serotonin increases vascular permeability and enhances the superoxide production by macrophages.⁸⁶

The more abundant α granules contain fibrinogen, RANTES, MIP-1 α , thrombospondin, P-selectin, PF4, PDGF, TGF- β , β -thromboglobulin, high-molecular-weight kininogen (HMWK), and many other biologically active proteins. PF4 and β -thromboglobulin initiate leukocyte recruitment and activation. PF4 induces neutrophil adherence to unstimulated endothelium and the release of secondary granules, whereas it inhibits monocyte apoptosis and promotes macrophage differentiation. PF4 can also stimulate histamine release from basophils. RANTES is deposited on the endothelium and recruits monocytes from the circulation. MIP-1 α is chemotactic for CD8⁺ T lymphocytes. PAF induces platelet aggregation, increases vascular permeability, and enhances phagocyte free radical formation and the adhesion of platelets to neutrophils. Platelet activation appears to occur in allergic asthma and may precede the delayed accumulation of eosinophils in the lung after allergen exposure. The α granules also carry several important growth factors, including vascular endothelial growth factor (VEGF), PDGF, and TGF- β . VEGF promotes extravasation and aids recruitment of leukocytes. PDGF is chemotactic for neutrophils and monocytes. TGF- β is chemotactic for and activates neutrophils and monocytes early during inflammation, but displays immunosuppressive effects during later stages of inflammation.⁸⁶

Platelets are an important source of eicosanoids, including thromboxane and prostaglandins F_{2 α} and E₂. Thromboxane synthetase in platelets is responsible for the production of thromboxane A₂ (TXA₂), a potent vasoconstrictor that also increases vascular permeability and stimulates platelet aggregation. Aspirin and other nonsteroidal anti-inflammatory drugs (NSAIDs) inhibit platelet function by inhibiting TXA₂ production. As this effect is irreversible, new platelets must be produced (7 to 10 days) to restore normal clot formation. PGF_{2 α} causes vasoconstriction, whereas PGE₂ vasodilates and modulates pain.^{90,91}

Platelets participate in transcellular lipoxygenase (LO) metabolism, which refers to the production of eicosanoids through interactions with neighboring inflammatory cells. Endothelial cells utilize platelet-derived endoperoxides to synthesize PGI₂. Platelets interact with neutrophils in several pathways, providing a direct link between thrombosis and inflammation. 12-Hydroxyeicosatetraenoic acid (HETE) released from activated platelets can be used by unstimulated neutrophils to produce the chemoattractant 12,20-HETE. 12-HETE and 5-HETE from activated platelets and neutrophils, respectively, can combine in either cell type to form 5,12-diHETE, an anti-inflammatory compound, which diverts production away from the proinflammatory leukotrienes. 12-LO from platelets and LTA₄ formed by neutrophils can produce the intermediate 5(6)-epoxytetraene. This intermediate produces lipoxins A₄ and B₄ that have primarily counterinflammatory functions.^{39,87,90,92}

In addition to modulating inflammation, platelets possess some direct microbicidal activity. Platelets are activated and degranulate when exposed to certain bacteria. Electron microscopic studies have shown that activated platelets internalize bacteria and viruses. The α granules contain antibacterial proteins called thrombocidins (TCs) in humans that support the killing of adherent bacteria. The two antibacterial proteins isolated from human platelets (TC-1 and TC-2) are bactericidal for *Escherichia coli* and *S. aureus*.⁸⁶

Noncellular Components

Cytokines. Cytokines are soluble protein mediators secreted by the cells of the innate and adaptive immunity in response to microbes and other antigens, including intra- and extracellular proteins, and mediate many of the functions of these cells (Table 6.6). They regulate and influence the host response to both pathogen-associated molecular patterns (PAMPs; i.e.,

acute and chronic bacterial, viral, fungal, and parasitic infections) and DAMPs (i.e., trauma, burns, allograft rejection, ischemia/reperfusion injury, and autoimmune disease). They govern lymphocyte differentiation during adaptive immunity and activate effector cells of both arms of inflammation to eliminate microbes. Cytokines play important roles in tumor biology as well as angiogenesis. Though essential for a normal immune response, excessive cytokine release underlies a variety of pathophysiologic inflammatory states such as acute respiratory distress syndrome (ARDS) and multiple organ dysfunction syndrome (MODS).^{93–96}

- 5 Cytokine secretion is brief, and as they typically are not stored preformed, necessitates transcription and de novo synthesis, which is also transient as the messenger RNA is unstable. Their functions are pleiotropic and redundant, which has been interpreted as a teleologic safety mechanism. However, such protective characteristics greatly limit the therapeutic utility of either cytokine administration or blockade. In fact, over 30 randomized controlled clinical trials have been conducted to assess the efficacy of agents modulating inflammation, in particular systemic cytokine concentrations, in reducing mortality. Yet only one, activated protein C, has been approved by the U.S. Food and Drug Administration (FDA) for use, and studies are ongoing to confirm its benefit.⁹⁷ Cytokines often influence the synthesis and actions of other cytokines, such as IL-1-induced T-cell IL-2 production; this interaction may be synergistic (additive or multiplicative) or antagonistic. They may function in an autocrine, paracrine, or

even endocrine function, although the inability to correlate plasma cytokine concentrations with the extent of tissue damage suggests that they are designed for local rather than systemic inflammation.^{4,39,93}

Their actions are mediated by specific membrane receptors on target cells to which they bind with high affinity (K_d α 10⁻¹⁰ to 10⁻¹²); hence, only minute quantities are necessary to elicit a response. Such efficiency is accompanied by a narrow therapeutic index and potential for unwanted global effects (i.e., MODS) with even small systemic concentrations. The receptors and the cells expressing them are regulated by external stimuli, which provides some degree of specificity to the response even though the cytokines themselves are not antigen specific. Receptor binding alters cellular gene transcription (induction or suppression) that may result in proliferation, differentiation, and the acquisition of new or suppression/enhancement of preexisting functions.⁴

All cytokine receptors consist of at least one transmembrane protein with an extracellular portion for ligand binding and an intracellular domain mediating signal transduction. Current receptor classification is based on structural homologies among the extracellular cytokine-binding domains. Type I cytokine receptors contain a domain with two conserved pairs of cysteine residues and a membrane proximal sequence of tryptophan-serine-X-tryptophan-serine, where X is any amino acid (WSXWS). Type II receptors resemble type I receptors; however, the WSXWS motif is absent. The Ig superfamily consists of receptors with extracellular Ig domains. TNF

receptors belong to a family of receptors with conserved cysteine-rich extracellular domains. Finally, seven-transmembrane α -helical receptors mediate the functions of cytokines called chemokines through GTP-binding (G) proteins.⁴

Translating ligand engagement to the signaling events that alter cellular phenotype involves a variety of signaling cascades dependent on the structure of the cytoplasmic tail of the particular receptor (Table 6.6). This is another method by which to classify cytokine receptors. These individual signaling cascades will be discussed in the context of the various cytokines and respective receptors employing them.

Early Cytokines/Innate Immunity

Tumor Necrosis Factor- α . TNF- α is the principal mediator in the initiation of the inflammatory response to gram-negative bacteria and other infectious pathogens. It is an important early mediator of inflammation and is essential for the normal initiation, maintenance, and repair of tissue injury. However, aberrant production may underlie the pathologic sequelae of many inflammatory and infectious states (i.e., MODS, rheumatoid arthritis, Crohn disease). Mononuclear phagocytes are the principal source of TNF- α , usually in response to the potent prototypical stimulus lipopolysaccharide.^{98,99} LPS-induced TNF- α production may be augmented by concomitant stimulation with IFN- γ , IL-4, and IL-10, whereas corticosteroids are suppressive.¹⁰⁰ Secondary sources include mast cells, NK cells, and T and B lymphocytes, and stimuli include complement C5a, GM-CSF, hypoxia, IL-1, NO, ROS, and TNF- α itself.³⁹

Shedding of extracellular domains of the two TNF- α receptors by metalloproteinases can further alter the biologic activity of TNF- α by decreasing the number of cell signaling sites on target tissues and increasing the amount of circulating inhibitors. Unlike other members of the TNF family that are primarily involved in regulation of cell proliferation, TNF- α has both proinflammatory and apoptosis-inducing properties.^{93,101}

TNF- α is expressed on the cell membrane as a bioactive protein and is cleaved into its soluble form by a specific TNF-

α -converting enzyme. There are two distinct TNF receptors present on virtually all cell types (Fig. 6.5).¹⁰² Ligand binding to TNF-RII leads to recruitment of TNF receptor-associated factors (TRAFs) that ultimately activate the transcription factors NF- κ B and AP-1 and thereby influence gene expression and cellular phenotype.⁴ Alternatively, binding to TNF-RI activates caspases and triggers apoptosis, in addition to signaling transcription factors. The manner by which either a proinflammatory or apoptotic path is chosen is unknown, although the net effect of TNF- α binding is probably the culmination of differential adaptor protein expression and downstream signal transduction cascades. TNF-RI appears to be more important in host defense as knockout TNF-RI mice show a greater degree of impairment in host defense than mice lacking TNF-RII.⁴

The principal function of TNF- α is to recruit neutrophils and monocytes to foci of infection and to activate these cells to eradicate microbes. TNF- α activates the endothelium to upregulate the expression of the adhesion molecules E- and P-selectin, ICAM-1, PECAM-1, and VCAM-1, and stimulates these cells and macrophages to secrete chemokines (IL-8, MIP-1 α , and Gro- α) that enhance the affinity of leukocyte integrins for their ligands and induce leukocyte chemotaxis and recruitment.¹⁰³ TNF- α also can induce HMGB1 release by activated macrophages, which generates a forward feedback mechanism, as HMGB1, by signaling through RAGE (see later), also induces TNF- α release.^{104,105} TNF- α induces a state of hypercoagulability by stimulating the release of tissue factor, PAF, von Willebrand factor, and thromboplastin. By inhibiting tissue-type plasminogen activator and thrombomodulin, it suppresses fibrinolysis, decreases protein C and S activation, and increases thrombin formation. However, TNF- α also induces the release of a variety of anticoagulants (prostacyclin), fibrinolytics (urokinase-type plasminogen activator), and vasodilators (NO, PGE₂), which may balance the tendency toward a procoagulant state. Most likely, the ultimate effect of TNF- α depends on the location and quantity in which it is produced and the vascular bed with which it interacts.^{4,93}

In severe infections, exuberant production and aberrant release of TNF- α enables it to function as an endocrine hormone

FIGURE 6.5. Tumor necrosis factor (TNF) receptor signaling pathway. (Redrawn from Abbas AK, Lichtman AH. *Cellular and Molecular Immunology*. Philadelphia: Saunders; 2003.)

and cause a plethora of pathologic sequelae. These systemic effects include fever (hence the name *endogenous pyrogen*) by stimulating the production of PGE₂ by the hypothalamus, acute-phase protein production by the liver, cachexia, inhibition of myocardial contractility and vascular tonus, and intravascular thrombosis due to loss of normal anticoagulant properties of the endothelium and the production of tissue factor. TNF- α is central to the pathogenesis of systemic inflammatory response syndrome (SIRS) and septic shock, and either state can be reproduced by administration of LPS or TNF- α .^{106–108} The organ dysfunction characteristic of either state may result from the hypercoagulability and subsequent tissue ischemia induced by this cytokine. Antagonists of TNF- α can prevent mortality in experimental models, but clinical trials with anti-TNF- α antibodies or with soluble TNF- α receptors have been to no avail.^{4,106}

Soluble TNF receptors formed by proteolytic processing of both types of receptors bind and neutralize TNF- α and serve as an endogenous regulator of cytokine activity.³⁹ Also, TNF- α directly induces the expression and release of TNF- α inhibitors, including IL-10, corticosteroids, and prostanooids, which in a negative feedback loop suppress TNF- α production and processing.⁹³ Hence, TNF- α serves as its own regulator.

Interleukin-1. Interleukin-1 functions similarly to TNF- α in mediating a proinflammatory host response to insult and is frequently released concomitantly with TNF- α (Table 6.6).¹⁰⁹ The major source of IL-1 is the mononuclear phagocyte. Synthesis and release are induced by LPS, cytokines (TNF- α , IL-2,

TGF- β , all the interferons), antigen–antibody complexes, C5, and hypoxia.⁹³ IL-1 is also produced by neutrophils, B cells, helper T cells, epithelial cells, fibroblasts, renal mesangial cells, and endothelial cells.

There are two forms of IL-1: IL-1 α and IL-1 β . Both forms are active, bind to the same receptors, and mediate the same effects. Most IL-1 found in the circulation is IL-1 β .⁴

The two IL-1 receptors (IL-1Rs) are members of the Ig superfamily. IL-1RI is universally expressed and transduces the majority of IL-1 responses.^{110,111} IL-1RII expression is restricted to B cells, but may be induced on other cells. There is little evidence that this latter receptor serves any function, and in fact, it may serve as a decoy.¹¹² The cytoplasmic portion of IL-1RI is homologous to a domain of Toll-like receptors (TLRs), which mediate the cellular response to endotoxin (Fig. 6.6). Engagement of IL-1 with IL-1RI induces the activation of the IL-1 receptor–associated kinase (IRAK) and the subsequent induction of the transcription factors NF- κ B and AP-1.^{4,111}

The functions of IL-1 mirror those of TNF- α , and synergy between the two cytokines is evident.¹⁰⁹ IL-1 activates endothelial cells to increase cell surface expression of adhesion molecules and the production of prostaglandins, PAF, and a variety of colony-stimulating factors. In doing so, it facilitates the recruitment and activation of appropriate leukocyte populations for specific localized immune responses. IL-1 also induces a procoagulant state by suppressing fibrinolysis through enhanced plasminogen activator inhibitor-1 and decreased tissue-type plasminogen activator activity and increasing thrombosis by stimulating tissue factor–like procoagulant and thromboplastin

FIGURE 6.6. Toll-like receptor (TLR) signaling pathway. (Redrawn from Abbas AK, Lichtman AH. *Cellular and Molecular Immunology*. Philadelphia: Saunders; 2003.)

production and suppressing thrombomodulin release. It induces the synthesis of PAF, a potent vasoconstrictor and stimulus for platelet and leukocyte activation. However, similar to TNF- α , it also stimulates the production of prostacyclin and urokinase-type plasminogen activator, which promotes an antithrombotic state.¹¹³ At larger concentrations, its effects become systemic, causing fever, the synthesis of acute-phase proteins, cachexia (inhibition of hunger and increased lipoprotein lipase activity), myalgia, somnolence, and hypotension. It stimulates arachidonic acid and prostaglandin metabolism and the release of pituitary stress hormones. It stimulates collagenase release and is a potent mitogen for neutrophils. Though similar in effect to TNF- α , probably by activating similar signaling cascades and transcription factors, IL-1 does not induce apoptosis, and even at high concentrations does not cause the physiologic derangements of septic shock.^{39,109}

Mononuclear cells produce the natural inhibitor of IL-1, IL-1ra. This IL-1 structural homologue is an inactive competitive inhibitor and may function as an endogenous regulator of IL-1. As with TNF- α , attempts to inhibit IL-1 have not been of clinical benefit in human trials of sepsis.³⁹

Chemokines. This is a large family of cytokines that primarily govern leukocyte chemotaxis, hence the name^{114–118} (Table 6.6). Those bound on the endothelial surface induce leukocyte integrins to express a high-affinity state for their ligands, which is critical for tight leukocyte adherence and subsequent migration into the extravascular space. However, they are also constitutively produced and assist in orchestrating the migration of immune cells into lymphoid organs. Unlike other chemoattractants, members of this family possess a degree of specificity, influencing the recruitment of discrete subsets of leukocytes. They mediate their effects both directly and indirectly through the induction of other mediators such as histamine and ROS. Though some chemokines, in particular those regulating cell traffic through tissues, are constitutively produced (MIP-3 β and RANTES), most necessitate cellular stimulation for synthesis and release, in particular, those involved in inflammatory reactions. They are typically produced by macrophages, leukocytes, endothelial cells, fibroblasts, and many other cell types stimulated by LPS, phagocytosis, and inflammatory cytokines such as IL-1, TNF- α , IL-6, and IFN- γ .³⁹

Chemokines can be classified into four families based on the number and location of N-terminal cysteine residues. The two major families are the CC chemokines, in which the cysteine residues are adjacent, and the CXC chemokines, in which one amino acid is interposed between these cysteine residues. This amino acid sequence appears to account for the disparate influence, either promotion or inhibition, on neutrophil chemotaxis. The three amino acids that immediately precede the first cysteine are critical in defining receptor binding and neutrophil activation.^{119,120} This area has been designated the ELR motif. The other two chemokine families are represented by lymphotactin (C chemokine) and fractalkine (CX3C chemokine).³⁹

Chemokine receptors are seven-transmembrane receptors that signal by G proteins and the formation of the second messengers, IP₃ and DAG (Fig. 6.4). Currently six CXC chemokine receptors, 11 CC receptors, and one receptor each for the last two subfamilies have been identified and defined. The pattern of cellular expression of the receptors determines the specificity of the cellular response to binding.^{4,120}

CXC chemokines primarily govern the chemoattraction and activation of neutrophils, and to a lesser degree lymphocytes, in particular T cells. At least 12 different chemokines have been identified. They are clustered on chromosome 4 and demonstrate 20% to 50% homology at the amino acid level. IL-8 is the prototypical CXC chemokine.⁹⁶ It is produced by an array of immune and nonimmune cells including monocytes, alveolar macrophages, neutrophils, keratinocytes, mesangial cells, epithelial cells, fibroblasts, and endothelial

cells. TNF- α and IL-1 are key molecules for inducing IL-8. It is chemotactic for all granulocytes and influences nearly every aspect of neutrophil function. It stimulates neutrophil degranulation, phagocytosis, transendothelial migration, and shedding of L-selectin, upregulation of β_2 integrins, and augments superoxide production. It is also a potent angiogenic factor. It binds to both CXCR1 and CXCR2, receptors that also engage the chemokines GCP-2, GRO- α , and ENA-78. ENA-78 is a potent neutrophil chemotaxin produced by the endothelium in response to TNF- α or IL-1, neutrophils, or monocytes. Studies have demonstrated that ELR-containing CXC chemokines are angiogenic, whereas those lacking this motif are angiostatic.^{39,93,119–121}

The interferon-influenced chemokines IP-10 and Mig do not target neutrophils, and the ELR motif is absent. They induce IFN- γ production and may play a more prominent role in mediating the inflammatory response to viral infections and autoimmune disorders. Mig is chemotactic for tumor-infiltrating lymphocytes, activated T cells, and monocytes and promotes CTL activity. IP-10 is chemotactic for monocytes, T cells, and NK cells and augments T-cell adhesion. Both chemokines bind the CXCR3 receptor found on IL-2-activated T cells. IFN- γ attenuates the expression of both IL-8 and ENA-78, and hence may serve as an important mechanism to the control and regulate inflammation.^{39,93} Stromal cell-derived factor-1 (SDF-1) is the only known ligand for the CXCR4 receptor and in the presence of IL-7 stimulates proliferation of pre-B-cell clones and growth of bone marrow B progenitor cells. The receptor has gained much interest since it was identified as a coreceptor for human immunodeficiency virus type 1 (HIV-1). Platelet factor 4 and neutrophil-activating protein-2 are CXC chemokines of platelet origin. PL-4 has angiostatic properties and inhibits the growth of various cancer cell lines in a manner that appears to be related to its angiostatic properties. It binds heparin with high affinity to stimulate coagulation.³⁹

The CC chemokines recruit monocytes, granulocytes, T cells, NK cells, and dendritic cells. RANTES is produced by stimulated T cells, platelets, and endothelial cells and is constitutively produced in resting T cells, which implies a homeostatic function. MIP-1 α and MIP-1 β are produced by activated T cells and are chemotactic for neutrophils, monocytes, eosinophils, basophils, and T lymphocytes. They are also mitogenic for hematopoietic progenitor cells and upregulate TNF- α , IL-1, and IL-6. The MCP family of chemokines influences the recruitment of monocytes and T cells. Their influence upon the function of these target cells is dictated by the cell's specific profile of receptor expression. MCP-1 is produced by nonlymphocytic cells (endothelial cells, epithelial cells, fibroblasts, smooth muscle cells, macrophages, and mast cells). Binding to CCR1 enhances chemotaxis, whereas activation of CCR2 increases the release of intracellular substances such as histamine and leukotrienes from basophils.³⁹

Lymphotactin is the only member of the C chemokine family and is produced by CD8⁺ lymphocytes, thymocytes, and NK cells and, to a lesser degree, by DCs and activated mast cells. It selectively recruits lymphoid cells.³⁹

Fractalkine is the sole CX3C chemokine and is produced by endothelium. In its membrane-bound form it may act as a solid-phase adhesion molecule, but upon cleavage serves as a soluble chemoattractant for lymphoid cells and monocytes.³⁹

Interleukin-12 (Natural Killer Cell Stimulatory Factor, Cytotoxic Lymphocyte Maturation Factor). IL-12 is integral in the innate immune response (Table 6.6). It is produced early during innate immune reactions against intracellular microbes and stimulates subsequent adaptive responses that confer further host protection against these pathogens; hence, it is an important link between innate and adaptive immune responses. IL-12 is critical for initiating a sequence of responses involving macrophages, NK cells, and T lymphocytes that results in the eradication of intracellular microbes. It is primarily

derived from activated mononuclear phagocytes and dendritic cells, and most importantly stimulates IFN- γ from T cells and NK cells. There are two pathways leading to IL-12 production: a T-cell-dependent and a T-cell-independent pathway. During innate immunity, LPS, infection by intracellular bacteria, and viral infections may induce IL-12 production. In addition, interactions between CD40 ligand and CD40 on activated lymphocytes and antigen-presenting cells, respectively, induce the release of APC IL-12.^{122,123} Thus, IL-12 is produced during the induction of and the effector phases of cell-mediated immune response when APCs present antigens to T cells.^{4,39}

The IL-12 receptor is a heterodimer composed of β_1 and β_2 subunits, the latter of which is involved in signaling, although both are required for engaging ligand. The receptor signals through the Janus kinase (JAK)/signal transduction and activator of transcription (STAT) pathway (Fig. 6.7).⁴ This signal transduction pathway is employed by numerous cytokines including IL-6, IL-12, IL-2, IL-7, IL-9, IL-4, and IL-10. A characteristic of this cytokine is the generation of a positive amplification loop, which heightens the inflammatory response. Expression of the IL-12 receptor is induced by IFN- γ . Activated NK cells and T_H1 cells produce IFN- γ that potentiates macrophage IL-12 production. IL-12 stimulates further production of IFN- γ by NK cells and T lymphocytes, which continues

FIGURE 6.7. JAK/STAT signaling pathway. JAK (Janus kinase) components are associated in an inactive form with the cytoplasmic portion of cytokine receptors. Cytokine binding leads to receptor aggregation. Adjacent JAK proteins become activated and phosphorylate each other and tyrosine residues. Through the Src homology domain, STAT (signal transduction and activator of transcription) proteins bind phosphorytyrosine residues on the cytoplasmic portion of cytokine receptors. Bound STAT proteins are phosphorylated by bound JAK proteins and subsequently dissociate. Phosphorylated STAT proteins dimerize and then move to the nucleus, where they induce transcription by binding to STAT-binding regions within the promoter. (Redrawn from Abbas AK, Lichtman AH. *Cellular and Molecular Immunology*. Philadelphia: Saunders; 2003.)

to fuel the reaction in a positive feedback mechanism. Ultimately, IFN γ activates macrophages to kill and degrade phagocytosed microbes. IL-12 potentiates bacterial LPS-induced macrophage TNF- α production. IL-12 antagonists reduce mortality in experimental models of LPS-induced septic shock; however, there is no evidence of their efficacy in human clinical trials.⁴

CD4⁺ helper T lymphocytes, under the influence of IL-12, differentiate into T_H1 cells, which subsequently activate phagocytes in cell-mediated immunity. It enhances the cytolytic functions of activated NK cells and CD8⁺ CTLs, and suppresses T_H2 cell differentiation and effector activity. The inhibition of T_H2 and IL-4 activity confers antiallergic properties to IL-12. IL-12 knockout mice demonstrate diminished IFN- γ production and defective T_H1 cell development and cell-mediated immunity against intracellular organisms.^{4,39}

Interleukin-6. IL-6 regulates the acute-phase response to inflammation, characterized by altered thermoregulation (i.e., fever), perturbation in nitrogen balance (i.e., cachexia and catabolism), and the generation of the acute-phase reactants of innate immunity by the liver (Tables 6.6 and 6.7).^{93,124} It functions in both innate and adaptive immunity to enable the host to recover. Despite in vitro data demonstrating that a variety of cells can produce IL-6, the most prominent in vivo sources of IL-6 are monocytes and macrophages stimulated with LPS or IL-1 or TNF- α –stimulated fibroblasts and endothelial cells.¹²⁵ Steroids inhibit the induction of IL-6. The receptor for IL-6 consists of cytokine-binding protein and a signal-transducing subunit, which belong to the type I cytokine receptor family. It signals through the JAK/STAT pathway (Fig. 6.7).⁴

In conjunction with IL-1 and TNF- α , IL-6 regulates the systemic manifestations of the acute-phase response.¹²⁴ It potentiates the immune response by inducing B-cell differentiation and activating T cells. It interacts with TNF- α to enhance T-cell proliferation and promotes neutrophil activation and accumulation. In adaptive immunity, IL-6 stimulates the growth of B

TABLE 6.7

ACUTE-PHASE PROTEINS

■ ACUTE-PHASE PROTEIN	■ FUNCTION
INCREASE	
C-reactive protein	Opsonin
Serum amyloid A	Apolipoprotein
α_1 -Acid glycoprotein	Platelet inhibitor
Fibrinogen	Coagulation, tissue repair
α_2 -Macroglobulin	Antiprotease
α_1 -Protease inhibitor	Antiprotease
α_1 -Antichymotrypsin	Antiprotease
Haptoglobin	Antioxidant
Hemopexin	Antioxidant
Ceruloplasmin	Antioxidant
C3	Complement
Factor b	Complement
C1 inhibitor	Complement
C4b-binding protein	Complement
Mannose-binding lectin	Complement
DECREASE	
Albumin	Transport
Prealbumin	Transport
Transferrin	Transport

lymphocytes that have differentiated into antibody-producing plasma cells. IL-6 antagonizes LPS-induced TNF- α production and TNF- α -induced IL-1 production.^{126,127}

High Mobility Group Box 1 Protein

HMGB1 was initially identified as an architectural chromatin-binding factor that bends DNA and directs protein assembly on specific DNA targets. It is abundant, ubiquitous, and evolutionarily conserved as evident by the 99% amino acid homology between rat and human proteins.⁵³ Thirty years after its original discovery, Tracey et al. demonstrated that HMGB1 acts as a late mediator of mortality in murine endotoxemia and sepsis. HMGB1 appeared 8 hours poststimulation and plateaued at 16 to 32 hours, very distinct from the acute rise and fall of early mediators (TNF- α , IL-1 β) of severe sepsis and septic shock.⁵³ Recent studies show that systemic concentrations are elevated in those patients who die of sepsis.¹²⁸

HMGB1 is the prototypical DAMP. When cells die by necrosis (i.e., nonprogrammed cell death), HMGB1 is released into the extracellular medium; in contrast, apoptotic cells modify their chromatin so that HMGB1 irreversibly binds, and thus is not released.^{129,130} However, HMGB1 may also be released by activated macrophages and NK cells via an active process that necessitates shuttling the protein from nucleus to cytoplasm; this event does not require further synthesis.^{129–131} Acetylation of HMGB1 appears essential for release; however, acetylation of histones, as occurs during apoptosis, strengthens its interaction with chromatin and inhibits release.^{129,130} Interestingly, though apoptotic cells do not release HMGB1, macrophages engulfing apoptotic cells do. Recent studies have shown that nucleocytoplasmic shuttling of HMGB1 involves serine phosphorylation by CaMK IV that enables it to be translocated to the cytoplasm by 14-3-3 and CRM1 chaperones.^{132,133} Subsequent release of cytoplasmic HMGB1 appears to involve active secretion through a secretory lysosomal pathway.^{129,131}

HMGB1 has many of the intercellular signaling activities characteristic of cytokines and therefore is often classified as a proinflammatory cytokine and potent regulator of the inflammatory response. In light of the fact that it is released by macrophages responding to bacterial challenge or by injured cells, it may mediate inflammation consequent to sepsis or trauma. After release, signaling is thought to occur by binding to RAGE with subsequent activation of p21ras, MEK, the MAPKs, and NF- κ B.^{104,134} This receptor is expressed on mononuclear phagocytes, vascular smooth muscle cells, and neurons. Blocking antibodies to RAGE fail to completely prevent cellular activation, suggesting the presence of an alternate receptor. Recent studies suggest that both TLR2 and TLR4 may mediate HMGB1-induced activation of NF- κ B in macrophages and neutrophils. This observation is very important as it demonstrates that a receptor classically considered specific for microbial danger signals may interact with an endogenous molecule.^{53,104,134}

HMGB1–RAGE interactions induce numerous proinflammatory events. Endothelial cells increase the expression of adhesion molecules and also secrete TNF- α and IL-8.¹³⁵ In neutrophils, HMGB1 activates MAPKs and enhances the expression of proinflammatory cytokines in an NF- κ B-dependent manner. In addition, it is chemotactic for neutrophils, monocytes, macrophages, and dendritic cells.¹³⁴ Intratracheal administration of HMGB1 to LPS-resistant mice stimulated lung neutrophil accumulation and the local production of proinflammatory cytokines.¹³⁴ HMGB1 has potent immunostimulatory actions and promotes the maturation of both myeloid and plasmacytoid dendritic cells. Systemic levels are markedly elevated in patients who die of sepsis, and animal studies suggest this association is causal.¹²⁸ Recombinant HMGB1 mimics the lethality of high-dose LPS and induces the

release of TNF- α by macrophages. However, intravenous administration of HMGB1 does not cause shock like TNF- α . In a series of elegant studies, anti-HMGB1 antibodies conferred a dose-dependent protection in animal models of endotoxemia, even when the first dose of anti-HMGB1 antibodies was delayed for 2 hours.⁵⁴ This occurred without changes in TNF- α , IL-1 β , or MIP-2 concentrations. Even more striking are the *in vivo* cecal ligation and perforation (CLP) models, in which anti-HMGB1 administration up to 24 hours after CLP significantly increased survival, 72% versus 28%.⁵⁴ This wider therapeutic window may enable the development of inhibitors of HMGB1 for treatment of sepsis.^{134,136–138} More recent data call into question whether HMGB1 can promote directly the secretion of proinflammatory cytokines (TNF- α , IL-1 α/β , IL-6, IL-8) and chemokines (MIP-1 α/β) as initially reported. A direct proinflammatory activity of HMGB1 has not been reproduced consistently, raising some concern that this might be based on the formation of specific complexes with other molecules such as LPS. Recent studies show that highly purified recombinant HMGB1 has very weak direct proinflammatory activity.¹³⁹

These observations have stimulated the search for other inhibitors of HMGB1. Ethyl pyruvate, a nontoxic food additive, dose dependently inhibits HMGB1 release and confers significant protection against the lethality of sepsis, even when the first dose is administered 24 hours after the onset of sepsis. In addition, it inhibits the translocation of NF- κ B and p38 MAPK signaling.^{134,136,140,141}

HMGB1 may also serve as a danger signal for other perturbations in homeostasis, as it can also be released passively by necrotic or injured cells but not apoptotic cells.^{130,138,142,143} Hypoacetylation of chromatin on the induction of apoptosis enhances HMGB1 binding, thereby preventing release during apoptotic processes. Thus, HMGB1 binding to chromatin depends on the viability of the cell and clearly distinguishes necrotic from apoptotic cells. This enables the innate immune response to respond to injury and further induce inflammation.^{130,138,142,143}

HMGB1 is also elevated during hemorrhage shock.¹⁴⁴ In a clinical case, serum HMGB1 levels increased significantly within 24 hours of hemorrhagic shock and returned toward basal levels as the clinical condition improved.¹⁴⁵ HMGB1 also appears to mediate cell damage and death in other noninfectious insults. In a model of warm liver ischemia/reperfusion, HMGB1 inhibition attenuates hepatocellular injury.³² Interestingly, this protection, as well as reduced systemic concentrations of HMGB1, was also afforded by inhibiting CaMK.³² High levels have also been found in other conditions of sterile inflammation such as rheumatoid arthritis.^{146–148} In human arthritis, overexpression of HMGB1 at the site of joint inflammation may be detected in the synovial fluid of rheumatoid arthritis patients.^{147,148} HMGB1 may in fact amplify the effect of local cytokines, as suggested by its ability to stimulate macrophages derived from synovial fluid of rheumatoid arthritis patients to release TNF- α , IL-1 β , and IL-6.^{146,149} Hence, HMGB1 may serve as a signal of danger from endogenous threats or perturbations.

Interleukin-15. IL-15 is produced by various cells in response to LPS and other stimuli, though the principal cellular source is mononuclear phagocytes (Table 6.6). It is structurally homologous to IL-2 as is its receptor and the IL-2R. IL-15 stimulates the proliferation of NK cells similarly to the manner by which IL-2 functions later in the adaptive immune response. It also acts as a T-cell growth and survival factor, especially for long-lived memory CD8⁺ T cells.⁴

Interleukin-18. IL-18 is structurally homologous to IL-1 and utilizes a similar IRAK signaling pathway (Table 6.6). Macrophages responding to microbial challenge or exposure to LPS are the principal source. Its primary function is to stimulate the production of IFN- γ by NK cells and T cells, and in

synergizing with IL-12, augments cell-mediated immunity. Knockout mice lacking IL-18 are deficient in IFN- γ production, and concomitant IL-12 deficiency eliminates all IFN- γ production and any T_H1 response.⁴

Interferons (Type I). Type I interferons possess potent antiviral and antitumor properties (Table 6.6). It is from this ability to interfere with viral infection that the name is derived. They are subcategorized into α and β interferons. Mononuclear phagocytes are the major source of interferon- α , whereas many cell types produce interferon- β . The most potent stimulus inducing the synthesis and release of either is viral infection, particularly double-stranded RNA produced during viral replication. Other inducers include IL-1, TNF- α , LPS, and antigen-activated T cells. Both groups bind to the same cell surface receptor and induce similar responses by signaling through the JAK/STAT pathway (Fig. 6.7).

These cytokines provide the first line of defense against viral infection and promote cell-mediated immunity against intracellular pathogen. They are secreted from virally infected cells to protect neighboring uninfected ones by inducing the synthesis of a number of enzymes that interfere with viral RNA or DNA transcription and viral replication. Through enhanced expression of class I MHC molecules, the type I interferons facilitate recognition of class I-associated viral antigens on infected cells by CTLs and increase the efficiency of CTL-mediated killing. Type I interferon stimulates the development of T_H1 cells by promoting these cells to express IL-12 receptor. They can also stimulate B-cell development, proliferation, and immunoglobulin heavy chain switching from IgM to IgG.^{150–152} Knockout mice lacking the receptor for these cytokines are susceptible to viral infections. Interferons are currently in clinical use for hepatitis B and C infection, multiple sclerosis, chronic myelocytic leukemia (CML), and Kaposi sarcoma.^{150–152}

Interleukin-10 (Cytokine Synthesis Inhibiting Factor). IL-10 inhibits activated macrophages and antigen-presenting cells and functions in a counterregulatory mechanism to suppress innate immune reactions (Table 6.6). It is produced mainly by macrophages, and hence functions by negative feedback. T lymphocytes, particularly the T_H2 subset, B cells, and some other nonlymphoid cells produce IL-10, in response to a variety of stimuli including LPS, TNF- α , IL-2, IL-4, and IL-13.

IL-10 binds to a type II (interferon) receptor. Though the manner by which it effects curtailment of the inflammatory response is unknown, its presence inhibits NK- κ B activation and the generation of inflammatory mediators perhaps by inhibiting, in some manner, the activation of signal transduction cascades and gene activation in proinflammatory pathways.^{4,153}

IL-10 terminates many of the functions of activated macrophages and participates in reestablishing homeostasis as the infection resolves. It downregulates proinflammatory cytokine (TNF- α , IL-1, IL-6, and IL-8) production, suppresses IL-12 production, and inhibits IFN- γ production and the innate and cell-mediated immune responses.^{4,56,93} It represses the expression of costimulators and class II MHC molecules on antigen-presenting cells, thereby terminating T-cell activation and inhibiting cell-mediated immunity.⁴ In neutrophils it inhibits cytokine release, superoxide generation, migration, and even survival.¹⁵⁴ In combination with IL-4, it inhibits IFN- γ release and IL-12 production to limit differentiation and function of T_H1 cells, favoring a T_H2 profile.⁵⁶

IL-10 knockout mice develop inflammatory bowel disease, which is hypothesized to result from unregulated macrophage reaction to enteric microbes.¹⁵⁵ In observational studies of ARDS or MODS, serum IL-10 levels were often elevated, and those patients with the highest systemic concentrations died.¹⁵³ It is unclear whether this is actually a pathologic response or merely a marker of disease severity. Contemporary belief is that

IL-10 is not a mediator of immunosuppression, but rather, important for immunoregulation.

Late Cytokines/Adaptive Immunity

Interleukin-2 (T-cell Growth Factor). Interleukin-2 stimulates the growth and proliferation of T lymphocytes and is responsible for T-cell clonal expansion after antigen recognition (Table 6.6).¹⁵⁶ IL-2 is produced by CD4⁺, and to a lesser extent CD8⁺ T cells. The receptor is heterotrimeric, consisting of three noncovalently associated proteins, α , β , and γ . The α and β chains are involved in cytokine binding, and the β and γ chains mediate signal transduction.⁴ Antigen recognition enhances the expression of functional IL-2 receptors, which confers a degree of specificity, as those T cells recognizing antigen are preferentially induced to proliferate in response to IL-2. Though the α chain appears on T-cell activation and binds IL-2, signal generation necessitates the β and γ chains. Cells expressing the complete α , β , and γ complex bind IL-2 with higher affinity (kD of 10^{-11} M), and growth stimulation of such cells occurs at a low IL-2 concentration.⁴ Upon antigen receptor-mediated T-cell activation, IL-2R α is rapidly upregulated, which reduces the concentration of IL-2 needed to stimulate growth. Therefore, antigen-stimulated T cells are more responsive to IL-2 than naïve T cells. This receptor signals through numerous signal transduction pathways including the JAK/STAT and MAPK pathways (Figs. 6.4 and 6.7).

IL-2 functions in an autocrine and paracrine fashion to induce the proliferation of the antigen-specific cells. After exposure to IL-1, there is a rise in cyclins and activation of cyclin-dependent kinases that stimulate the progression from the G1 to the S phase of the cell cycle. A reduction in p27, an inhibitor of cyclin-kinase complexes, facilitates this progression, and the induction of Bcl-2, an antiapoptotic protein, facilitates survival. It also stimulates the production of other cytokines such as IFN- γ and IL-4.⁴

IL-2 promotes the proliferation and differentiation of many immune cells. NK cells are stimulated to grow and transform into lymphocyte-activated killer (LAK) cells. In combination with IFN- γ and IL-12, IL-2 can trigger a positive feedback cycle of NK activation. IL-2 stimulates B-cell growth and antibody synthesis. Repeated activation of CD4⁺ T cells in the presence of IL-2 sensitizes these cells to apoptosis by Fas-Fas-ligand. IL-2 may also stimulate the development of regulatory T cells, and IL-2 knockout mice develop autoimmunity. Knockout mice lacking the γ chain develop X-linked severe combined immunodeficiency syndrome. This is probably due to an inability of immature T cells to respond to IL-7. IL-2 has been used in the management of cancer, in particular renal cell carcinoma.¹⁵⁷

Interleukin-4. IL-4 is the major stimulus for the production of IgE antibodies and for the development of T_H2 cells from naïve CD4⁺ T cells (Table 6.6). The principal cellular sources are CD4⁺ T cells, mast cells, and basophils. The IL-4 receptor belongs to the type I cytokine receptor family and signals through the JAK/STAT pathway¹⁵⁸ (Fig. 6.7). IgE is integral in orchestrating the defense against parasitic infections. It stimulates IgE production and mast cell/eosinophil-mediated reactions, and induces B-cell Ig heavy chain class switching to the IgE isotype. However, IL-4 also serves a counterregulatory role by inducing T_H2 cell differentiation and growth. IL-4 antagonizes the macrophage-activating effects of IFN- γ and thus inhibits cell-mediated immunity.

Interleukin-5. IL-5 is produced by T_H2 cells and activated mast cells and activates eosinophils (Table 6.6). It signals through the type I cytokine receptor and the JAK/STAT pathway (Fig. 6.7). IL-5 is an inducer of eosinophil growth, differentiation, and activation, and also participates in the eradication of helminthic infection. IL-5 also stimulates the proliferation of B cells and the production of IgA antibodies.⁴

Interleukin-13. IL-13 is produced by T_H2 cells and some epithelial cells and is structurally homologous and functionally similar to IL-4 (Table 6.6). The receptor is found mainly on nonlymphoid cells and can be activated by either IL-13 or IL-4. IL-13 downregulates the expression of Fc γ on monocytes and macrophages, thereby decreasing antibody-dependent cellular cytotoxicity. It increases 15 S-HETE and lipoxin A_4 , both of which antagonize proinflammatory leukotrienes. However, they can increase the expression of MHC class II and costimulatory molecules on monocytes and thereby serve an immunostimulatory function. The major action is to inhibit the activation of macrophages and to antagonize IFN- γ .¹⁵⁹

Interferon- γ . IFN- γ is produced by NK cells, T_H1 cells, and CD8 $^+$ cells, and as the principal stimulus for macrophage activation, provides necessary functions during both innate and adaptive immune responses (Table 6.6). It modulates cellular differentiation, cytotoxicity, cytokine production, cellular adhesion, and oxidative metabolism. During innate immunity, NK cells secrete it upon exposure to pathogen or IL-12. CD8 $^+$ T cells and the T_H1 subset of CD4 $^+$ T cells produce it in response to MHC-bound peptide antigen with a costimulatory signal. The IFN- γ receptor is composed of two homologous proteins belonging to the type II cytokine receptor family and functions through the JAK/STAT pathway (Fig. 6.7).⁴

The antiviral and antitumor properties of IFN- γ are redundant with those of type I interferons. In concert with TNF- α and IL-12, it forms one arm of a positive feedback loop fueling the activation of both NK cells and macrophages. Stimulated macrophages activate NK cells by releasing TNF- α and IL-12. These NK cells produce IFN- γ , which further stimulates macrophages to secrete more TNF- α and IL-12.^{160,161}

IFN- γ induces the genes encoding the enzymatic machinery required for generating reactive oxygen species generation and provides the principal stimulus for macrophages to kill phagocytosed microbes. It regulates the expression of MHC class I and class II molecules and costimulators of APC, and induces the transcription of enzymes regulating antigen processing.^{160,161}

IFN- γ synergizes with TNF- α to activate the endothelium and upregulate adhesion molecule expression; in doing so it facilitates lymphocyte recruitment and leukocyte recruitment. Interferon promotes the differentiation of naive CD4 $^+$ cells into T_H1 cells and inhibits the proliferation of T_H2 cells, in part by inducing IL-12, the major T_H1 -inducing cytokine, from activated mononuclear phagocytes. It promotes B-cell switching to certain IgG subclasses, notably IgG2a, and inhibits the switching to IL-4-dependent isotypes such as IgE and IgG1. These IgG subclasses bind the Fc γ receptors on phagocytes and activate complement, thereby promoting phagocytosis of opsonized microbes. It activates PMNs and stimulates the cytolytic activity of NK cells. The net effect is to promote macrophage-rich inflammatory reactions while inhibiting IgE-dependent eosinophil-rich reactions. IL-10, by suppressing macrophage release of TNF- α and IL-12, negatively regulates IFN- γ production.

IFN- γ also demonstrates counterregulatory properties. It selectively inhibits LPS-induced expression of CXC chemokines. It upregulates macrophage production of IP-10, MIG, and ELR-negative chemokines that inhibit neutrophil chemotaxis and activation and decreases macrophage release of ELR-positive CXC chemokines (e.g., IL-8), which are chemotactic for neutrophils.⁴

Transforming Growth Factor- β . TGF- β is a homodimer synthesized and secreted by activated T cells, macrophages, and many other cells (Table 6.6). It is primarily immunosuppressive and inhibits the proliferation and activation of lymphocytes and other leukocytes. It promotes wound healing by increasing extracellular matrix protein synthesis and stimulating mononuclear cell and fibroblast influx.^{162–164} Though the family consists of three closely related isoforms, most cells uti-

lize TGF- β . Its effects are mediated through two high-affinity TGF receptors (type I and II) that signal through a serine/threonine kinase domain that phosphorylates transcription factors called SMADS.⁴

TGF- β inhibits the proliferation and differentiation of T cells and the activation of macrophages. It favors differentiation of CD4 $^+$ cells to the T_H2 subset and inhibits MHC class II surface expression. By suppressing the expression of MHC class II antigen, it abrogates the adaptive immune response. Macrophages demonstrate diminished ROS production and TNF- α and NO release. It directly counteracts the influence of proinflammatory cytokines on PMNs and endothelial cells, and in combination with IL-4, IL-13, and IL-10 can antagonize the production or effects of these proinflammatory mediators. Knockout mice deficient in TGF- β develop uncontrolled inflammatory lesions.^{4,39}

Cytokines That Stimulate Hematopoiesis. Cytokines are necessary for normal hematopoiesis. Several of the cytokines stimulated during both innate and adaptive immune responses are mitogenic for and induce differentiation of bone marrow progenitor cells.

CSFs are cytokines made by activated T cells, macrophages, endothelial cells, and bone marrow stromal cells that stimulate increased production of inflammatory leukocytes by bone marrow progenitors. Receptors for GM-CSF and G-CSF are of the class I family of cytokine receptors. GM-CSF is expressed by T and B cells, macrophages, mast cells, fibroblasts, and endothelium in response to stimuli such as IL-1, IL-2, LPS, and TNF- α . It stimulates neutrophils, monocytes, macrophages, and DCs and is a powerful inducer of hematopoiesis. It enhances cytokine release, degranulation, and phagocytosis of opsonized particles in neutrophils. In monocytes and macrophages it enhances cytotoxicity and cytokine release. It promotes the activity of APCs and the maturation of bone marrow cells into dendritic cells and monocytes.¹⁶⁵ G-CSF is produced by macrophages, endothelial cells, fibroblasts, and bone marrow stromal cells. It functions as an endocrine hormone to mobilize neutrophils and induces subsequent leukocyte proliferation and maturation. In 1991, the FDA approved G-CSF for use in patients with neutropenia.^{166,167}

Stem cell factor or c-Kit ligand is synthesized by marrow stromal cells and binds to a cell surface tyrosine kinase receptor on pluripotent stem cells that is the protein product of the cellular proto-oncogene c-kit. Its effects appear permissive, as it is corequisite for stem cell responsiveness to other colony-stimulating factors, yet in isolation does not stimulate colony formation. It may also play a role in sustaining the viability and proliferative capacity of immature T cells in the thymus.⁴

IL-3 is a product of CD4 $^+$ T cells that promotes the differentiation of immature marrow progenitors into all known mature cell types. It also promotes the growth and development of mast cells. Surprisingly, despite these important functions, murine knockouts do not manifest noticeable impairment of hematopoiesis.⁴

IL-7 is secreted by bone marrow stromal cells and promotes the growth and survival of immature precursors committed to the B- and T-lymphocyte lineages. Knockout mice, deficient in IL-7 or its receptor, are lymphopenic with diminished populations of B and T cells.⁴

The Complement System

- 6 The complement system is integral to both innate and adaptive immunity. It has the capacity to independently eliminate organisms and to facilitate host defense by marking foreign particles for phagocytosis through opsonization. Many pathophysiologic inflammatory diseases, immune complex diseases, ischemia/reperfusion injury, and ARDS are considered consequences of aberrant function of this system.^{168–171}

The system consists of three pathways composed of approximately 30 serum and cell surface proteins that interact with one another and with other molecules of the immune system in a highly coordinated fashion. These cascades involve the sequential proteolytic activation of zymogens to generate enzymes with proteolytic activity. This mechanism for activation amplifies the response because each individual enzyme activated can cleave numerous zymogens in the next step and generate multiple activated enzyme molecules. Ultimately, the products of complement activation adhere to microbial cell surfaces or to antibody-bound microbes and other antigens to directly or indirectly eliminate these pathogens. Temporal and spatial regulation to the focus of infection is ensured both by the transience of activation of these enzymes in the absence of microbes or antigens and by several circulating proteins that provide surveillance.^{168,170}

The complement cascade is divided into three distinct pathways: the classical pathway (humoral immunity), which is activated by antibody bound to antigen; the alternative pathway (innate immunity), in which complement is activated by components of microbial cell surfaces; and the mannose/lectin pathway (innate immunity), which is activated by a plasma lectin that binds to mannose residues on microbes. Despite differences in which the cascade is activated, all three complement pathways ultimately result in the cleavage of C3 and share the same subsequent late cascade.^{168,170}

The alternative pathway functions in the absence of antibody and is phylogenetically the oldest pathway (Fig. 6.8). Bacteria, viruses, fungi, and parasites all function as stimuli. Initial activation begins with the cleavage of C3 and the stable attachment of its product C3b to the microbial surface. Bound C3b binds factor B, which is subsequently cleaved by a plasma serine protease called factor D to generate Bb. The C3bBb complex is called the alternative pathway C3 convertase and functions to cleave more C3. In doing so the convertase serves as an amplification step in both the classical and alternative pathways. Properdin prolongs the half-life of C3 convertase by delaying the release of Bb from C3bBb. C3b is the recognition component of the alternate pathway and is responsible for the opsonization of bacteria. C3a in conjunction with C5a and C4a induces acute inflammation by activating mast cells and neutrophils. These inflammatory mediators play a significant role in increasing blood vessel permeability, vasodilatation, edema formation, neutrophil adhesion and activation, chemotaxis, and the release of toxic oxygen species and lysosomal enzymes from phagocytic cells. The binding of another C3b to this complex generates the alternative pathway C5 convertase, C3bBbC3b.^{4,168,170}

Activation of the alternative pathway is restricted to the cell surface of microbes, as mammalian cells possess several regulatory proteins to rapidly degrade any C3bBb. Excessive amplification is regulated by β 1H globulin factor H and factor I. H accelerates the decay and delays the formation of C3bBb. It also acts as a cofactor for I to degrade C3 into iC3b, which is unable to bind B to generate C3 convertase. Decay acceleration factor (DAF) hinders C3 convertase assembly and mediates its dissociation in all three pathways. Also, the protein properdin, which stabilizes this alternative pathway C3 convertase, has a higher affinity for microbial than mammalian cell surfaces.^{4,168,170}

The classical pathway is the primary mediator of adaptive humoral immunity and is initiated by binding of the complement protein C1 to IgG or IgM molecules engaged with antigen (Fig. 6.8). Other substances such as lipid A in endotoxin and mitochondrial membranes may activate this pathway independent of antigen-antibody complexes in vitro.^{168,172}

C1 is a calcium-dependent trimeric protein consisting of C1q, which recognizes and binds the Fc region of the immunoglobulin, and C1r and C1s, which are proteases. C1q engages the Fc portion of the immunoglobulin μ and γ heavy chains. Each Fc region has a single C1q binding site, yet for activation, each C1q molecule must bind to two Ig heavy chains. Hence, multiple antibodies must be approximated for activation, which restricts activation to foci of immunoglobulin engagement. IgM exists as a pentamer enabling it to bind to two C1q molecules, and hence it is more efficient at complement activation.^{4,168,172}

Interaction between C1q and the immunoglobulin Fc region induces a conformational change in C1q that activates C1r, which subsequently cleaves and activates C1s. C1s cleaves C4 to generate C4b and C4a. The C4a anaphylatoxin possesses properties similar to those described for C3a. C4b localizes to immune complexes on the cell surface. C2, after complexing with C4b, is cleaved by C1s, thereby generating the classical C3 convertase C4b2a complex, which has the ability to cleave C3. The C3b generated can bind Bb, producing more C3 convertase and amplifying the signal. The key early steps of the alternative and classical pathways are analogous: C3 and factor B of the alternative pathway are homologous to C4 and C2 in the classical pathway. C3b can also combine with the classical C3 convertase to generate C4b2a3b, the classical C5 convertase.⁴

Numerous regulatory mechanisms exist to restrict activation to sites of inflammation. Excessive classical C3 convertase activity is prevented by the rapid decay of C2a from the complex, which renders the complex unstable. C1 inhibitor

FIGURE 6.8. Complement pathways. **Alternate pathway:** 1. C3 is cleaved to C3b. 2. C3b binds and cleaves B to Bb to form C3 convertase (C3bBb). 3. Another C3b binds C3 convertase to form C5 convertase (C3bBbC3b). **Classical pathway:** 1. C1 binds immunoglobulin. 2. C1 binds and cleaves C4 and C2 to C4b and C2a to form C3 convertase (C4b2a). 3. C4b2a binds another C3b to generate C5 convertase (C4b2aC3b). **Late pathway:** 1. C5 convertase cleaves C5 to form C5b, which integrates into the plasmalemma. 2. C6–8 are recruited, forming the C5b–8 complex. 3. C5b–8 recruits numerous C9 subunits, which form a pore in the pathogen cell wall. (Redrawn from Abbas AK, Lichtman AH. *Cellular and Molecular Immunology*. Philadelphia: Saunders; 2003.)

covalently binds C1s, reducing the half-life of activated C1 to only 13 seconds. C4-binding protein enhances spontaneous dissociation of C4b2a and also acts as a cofactor for C3b/C4b inactivator, which degrades C4b.³⁹

The mannose-binding lectin (MBL) pathway is activated by the binding of microbial polysaccharides to circulating lectins; mannose-binding lectin serves as the recognition unit of the MBL pathway. This pathway recognizes polysaccharides with high mannose content and other oligosaccharides with characteristic linkages found exclusively on pathogens and not on normal host components. Binding is calcium dependent and results in the activation of mannose-binding lectin-associated serine proteases (MASP-1 and MASP-2). Activated MASP-2 cleaves and activates C4 and C2 in the same fashion as the classical complement pathway. Subsequent steps of complement activation of the MBL pathway mirror those of the classical complement pathway.^{168,173,174}

The C5 convertases generated during either the classical or alternative pathway initiate a cascade of events that culminates in the formation of the cytotoxic MAC. Specifically, C5 convertase cleaves C5, yielding C5a and C5b. C6 and C7 bind to generate the C5b67 complex. This hydrophobic moiety penetrates deeply into the lipid bilayer as a high-affinity receptor for C8. Binding of C8 forms the complex C5b-8 that recruits numerous C9 subunits, which polymerize to form pores in the plasma membrane. The pores structurally resemble the membrane pores formed by perforin, the cytolytic granule protein found in CTLs and NK cells. Their diameter may span 100 angstroms, which prevents the maintenance of vital ionic gradients and induces osmotic lysis and, ultimately, the death of target cells or pathogens. Patients with deficiencies in the terminal components of C5, C6, C7, and C8 are susceptible to meningococcal and gonococcal infections.^{4,175} By contrast, recent studies suggest that aberrant induction of the complement system, specifically C5a, plays an integral role in inducing paralysis of the innate immunity and the development of ARDS and MODS.

The effects of complement are in part mediated through several complement receptors. Opsonization and phagocytosis are important mechanisms for pathogen destruction, and phagocytic cells express receptors for complement factor C3 components. Complement receptor type 1 (CR1), the C3b receptor for C3b and C4b, mediates engagement of and facilitates phagocytosis of complement-bound microbes and the clearance of immune complexes from the circulation. It is expressed on a variety of cells including RBCs, neutrophils, monocytes, eosinophils, and T and B cells. RBCs facilitate elimination by transporting these opsonized particles to the liver and spleen where the immune complexes are removed by phagocytes. CR2 stimulates humoral immune response by enhancing B-cell activation by antigen and by promoting the trapping of antigen-antibody complexes in germinal centers. In humans, this receptor is the receptor for Epstein-Barr virus (EBV). CR3 and CR4 are β_2 integrins that bind the iC3b-processed fragment of C3 and promote macrophage and neutrophil phagocytosis of iC3b-opsonized antigen.^{4,39}

This entire cascade is under strict regulation to ensure that any activation is restricted to sites of inflammation and infection. Several circulating proteins function to do this. This regulation is needed as low-level activation is always occurring, and if not quelled, would certainly damage normal tissues. Even when locally activated, byproducts may damage nearby cells and tissues.

C1r and C1s are inhibited by C1 inhibitor, a serine protease inhibitor that mimics C1r and C1s. C1 inhibitor targets activated C1qrs, and after attachment, C1r-C1s dissociate and activation of classical complement ceases. This inhibition prevents the accumulation of active C1r-C1s, thereby limiting the duration during which active C1r-C1s can initiate the cascade.⁴ C1 inhibitor also inhibits other circulating inflammatory serine pro-

teases including kallikrein and factor XII, both of which can activate the formation of bradykinin.⁴ Hereditary angioneurotic edema is an inherited deficiency of C1 inhibitor and manifests as acute intermittent edema of the skin and mucosa causing abdominal pain, vomiting, diarrhea, and airway obstruction.

MCP, CR1, and DAF are regulatory proteins that bind to C3b and C4b deposited on cell surfaces and competitively inhibit the binding of other components of the C3 and C5 convertases, such as Bb and C2a, and thereby block further progression of the cascade. These proteins are only produced by mammalian cells. Deficiency of an enzyme required to form the linkages necessary to express DAF underlies paroxysmal nocturnal hemoglobinuria, a disease characterized by recurrent intravascular hemolysis due to unregulated complement activation on the surface of erythrocytes. Cell-associated C3b is proteolytically degraded by a plasma serine protease called factor I, which is active only in the presence of regulatory proteins such as MCP, factor H, C4BP, and CR1. MAC formation is inhibited by CD59, a membrane protein that incorporates itself into growing MACs and inhibits the incorporation of C9. It is not present in microbes. The function of these regulatory proteins may be overcome by increasing amounts of complement activation.⁴

Lipid Mediators

Eicosanoids. Eicosanoids are 20-carbon lipid inflammatory mediators derived from membrane arachidonic acid that are involved in numerous homeostatic processes and inflammation. These lipid mediators are not stored in tissues, but are synthesized *de novo* within seconds in response to a variety of stimuli, including mechanical trauma, or specific cytokines, growth factors, and other mediators (Fig. 6.9). Although most cells are capable of producing eicosanoids, neutrophils and macrophages are the predominant source during inflammation. They are rapidly degraded in the circulation, which limits their role primarily to that of autocrine and paracrine mediators of local inflammatory changes.¹⁷⁶⁻¹⁷⁸

The liberation of the precursor molecule, arachidonic acid, is the major rate-limiting step. The family of PLA₂, in particular type IV cytosolic PLA₂, is responsible for eicosanoid production; cells lacking type IV PLA₂ are devoid of eicosanoid synthesis.¹⁷⁹ Many PLA₂ are transcriptionally regulated by IL-1 and TNF- α , whereas others are regulated by the MAPK pathway and by calcium-dependent translocation to membranes. Once formed, arachidonic acid metabolism proceeds along one of two pathways.¹⁷⁶⁻¹⁷⁸

Cyclooxygenase Pathway (Prostaglandins). Cyclooxygenase catalyzes the initial step of a series of reactions that converts arachidonic acid to prostanoids (Fig. 6.9). There are two isoforms, COX1 and COX2; the former is constitutively expressed, whereas COX2 is inducible. COX2 is considered more important during inflammatory processes such as fever, hyperalgesia, and edema formation. Either enzyme catalyzes the conversion of arachidonic acid to the endoperoxidase PGG₂, which is subsequently converted to PGH₂. PGH₂ serves as the precursor to numerous specific prostaglandins. All of these products possess very short half-lives and are rapidly inactivated.^{179,180}

Prostaglandins mediate their effects through G-protein signaling (Table 6.8). Prostacyclin (PGI₂) is produced by the endothelium as a potent vasodilator and inhibitor of platelet aggregation and adhesion, characteristics that enhance tissue perfusion. PGI₂ inhibits neutrophil chemotaxis and activation and interacts synergistically with PGE₂ to increase vascular permeability through the bradykinin pathway. PGE₂ is the predominant anti-inflammatory prostaglandin and is produced by nearly all inflammatory cells. It is produced in response to IL-1 and mediates the hypothalamic fever response and synergizes

with bradykinin and histamine to mediate pain. It is a bronchodilator, inhibits both IL-1 production and T-cell responsiveness to IL-1, and at low concentrations suppresses TNF- α production. It also inhibits neutrophil chemotaxis and activation and T_H1 lymphocyte proliferation.^{179,180} There is some suggestion from animal studies that PGE₂, PGE₁, and PGI₂ may be beneficial in response to sepsis through their endogenous counterregulatory properties. Administration of each of these has been shown to improve survival in several animal models of hypovolemic and traumatic shock, though clinical trials have failed to identify benefit.¹⁸⁰ PGD₂ is a potent bronchoconstrictor that inhibits neutrophil chemotaxis and activation. TXA₂,

PGG₂, and PGH₂ oppose the actions of prostacyclin by promoting platelet aggregation and inducing bronchoconstriction. TXA₂ produced by platelets and macrophages is a powerful vasoconstrictor that induces neutrophil accumulation and increases vascular permeability.^{176–178,181} There is substantial evidence that TXA₂ plays a significant role in early acute-phase organ injury.¹⁸⁰

Lipoxygenase Pathway (Leukotrienes and Lipoxins).

Leukotrienes and lipoxins are leukocyte-derived molecules synthesized by the oxidation of arachidonic acid by one of three LO enzymes: 5-LO, 12-LO, and 15-LO (Fig. 6.9). 5-LO

associates with the perinuclear membrane protein 5-LO-activating protein (FLAP) to catalyze the formation of 5-hydroperoxyeicosatetraenoic acid (5-HPETE). 5-HPETE is subsequently converted to LTA₄ by the combined efforts of a dehydrase and 5-LO. LTA₄ serves as the precursor for either LTB₄ or LTC₄. LTC₄ can in turn be successively hydrolyzed to the dipeptide derivative LTD₄ and the LTE₄. Additional LO activity results in the production of 12-HPETE, 12-HETE, and 15-HPETE. These compounds exhibit biologic activity, although they are not as potent as the leukotrienes or prostaglandins. The leukotrienes are inactivated by oxidation followed by dehydration.^{177–179,181,182}

The major lipoxygenase product of neutrophils is LTB₄, though macrophages may also synthesize this compound. This compound is potentially chemotactic for both neutrophils and eosinophils, and by upregulating endothelial cell surface adhesion molecules promotes leukocyte recruitment. It increases vascular permeability, either directly or through interaction with neutrophils and endothelial cells. LTB₄ has also been shown to induce hyperalgesia.^{92,179}

LTC₄, LTD₄, and LTE₄ comprise the family of slow-reacting substances of anaphylaxis (SRSA), compounds synthesized by mast cells during anaphylactic reactions. LTC₄ is the major eicosanoid product of eosinophils and the only mast cell-derived product of LO. These three leukotrienes are potent vasoconstrictors and the most powerful bronchoconstrictors in humans, being three orders of magnitude more potent than histamine. They also increase vascular permeability and are vasodilatory in skin.^{43,179}

Lipoxins are biosynthesized by several routes in a tissue-specific manner. Current evidence implicates the eosinophil. A 5(6)-epoxytetraene intermediate can be formed by 5-LO activity on 15-HPETE. This reaction when carried out in blood vessels requires the interaction between platelets and neutrophils. On mucosal surfaces, 12-LO and 5-LO activity on LTA₄ can result in formation of this lipoxin intermediate through leukocyte-epithelial interactions. The 5(6)-epoxytetraene intermediate is then converted to lipoxin A₄, lipoxin B₄, or lipoxin C₄, the last of which serves as the precursor for lipoxins D₄ and E₄.^{90,183,184}

Though many of the functions of lipoxins have yet to be elucidated, they appear to counterregulate the actions of leukotrienes. They inhibit leukotriene production by downregulating 5-LO as 15-LO is upregulated. The anti-inflammatory cytokines IL-4 and IL-13 further contribute to suppression of inflammatory responses by enhancing 15-LO activity. In addition to inhibiting synthesis, lipoxins inhibit the actions of LTB₄ and LTD₄. Lipoxins A₄ and B₄ are potent vasoactive compounds, though this effect is tissue specific for lipoxin B₄, as it induces vasoconstriction in some tissue beds. Lipoxins influence smooth muscle and vascular tonus by increasing NO and prostacyclin production, increasing arachidonate release, and reversing endothelin-induced vasoconstriction. Counterinflammatory functions of lipoxin A₄ include inhibition of leukotrienes, fMLP, and other chemoattractants. Lipoxin A₄ also downregulates LTB₄-mediated delayed-type hypersensitivity reactions.^{90,183–185}

A large number of anti-inflammatory drugs, many of which are in clinical use, act by interfering with eicosanoid synthesis. The anti-inflammatory properties of corticosteroids are mediated at least in part by the inhibition of PLA₂ through the induction of lipocortin. They have been shown to selectively inhibit COX2 activation without affecting COX1. NSAIDs block the synthesis of both prostaglandins and thromboxanes by inhibiting COX activity. In contrast to the other NSAIDs, aspirin inhibits COX in an irreversible manner, and restoration of platelet function necessitates the administration of platelets. Recently aspirin, by either acetylating COX2 or by inducing the oxidation of arachidonic acid by cytochrome P450 or 5-LO, has been shown to stimulate the formation of 15R-HETE in endothelial or epithelial cells. These 15-epilipoxins exhibit higher potency in suppressing inflammation because of their

prolonged half-lives. A potential complication of NSAID use and COX inhibition is the shunting of arachidonate through the 5-LO pathway and subsequent greater production of proinflammatory leukotrienes (asthma); such consequences minimize any benefit achieved from reducing other eicosanoid levels. In addition, NSAIDs act systematically in a nonselective manner, so that inhibition of prostaglandin synthesis can result in dangerous side effects in locations where prostaglandins normally exert cytoprotective effects (stomach).^{180,184,186}

Platelet-activating Factor

PAF is a heterogeneous mixture of 1-O-alkyl-2-acetyl-sn-glycero-3-phosphocholines that plays a prominent role in both physiologic and pathologic inflammatory states. It does not exist preformed, but is rapidly produced by activated cells. Synthesis involves either the remodeling of membrane phospholipids by PLA₂, usually more important under inflammatory conditions, or de novo synthesis as occurs in resting cells. De novo synthesis is regulated by substrate availability and involves a constitutively active enzyme that produces PAF in small basal amounts.¹⁸⁷ The membrane phospholipid precursor is present in high amounts in neutrophils. Other cells that can synthesize PAF include platelets, basophils, monocytes, eosinophils, mast cells, and vascular endothelial cells. Similar to eicosanoid production, the synthesis of PAF is initiated by calcium-dependent activation of PLA₂, which yields 1-O-alkyl-sn-glycerophosphocholine (lyso-PAF); subsequent acetylation generates PAF. PAF may be released from the cell, or it may be converted back to lyso-PAF by an acetylhydrolase and to the precursor ether-phosphatidylcholine.¹⁸⁷

The actions of PAF are mediated by G-protein activation. As the name implies, PAF induces platelet aggregation and degranulation, yet also possesses many other critical functions for inflammation. Its vasoactive properties include vasodilation and increased permeability, and it is an equally potent bronchoconstrictor. PAF enhances arachidonic acid metabolism, leading to increased leukocyte motility, degranulation, and free radical formation. PAF plays an integral role in promoting activation and adherence of inflammatory cells to the endothelium.¹⁸⁸ During the early inflammatory response, activated endothelial cells synthesize and express PAF on the cell surface. Leukocytes tethered by selectins to the endothelium are activated by endothelial PAF, which results in the induction of tight integrin-dependent adhesion and subsequent emigration and chemotaxis toward the inflammatory focus. Acyl-PAF, the major acetylated lipid from mast cells, basophils, and endothelial cells, is a less potent derivative of PAF that likely plays a similar role in the regulation of neutrophil recruitment. PAF also promotes platelet and neutrophil aggregation, thereby contributing to the prothrombotic state of acute inflammation. In circumstances of persistent pathologic stimuli, PAF may be liberated systemically, thereby causing the sequelae of an excessive inflammatory response. As a mediator of sepsis, PAF augments endotoxin-induced hypotension and neutrophil and platelet accumulation in the lungs. There is evidence that the NO-induced hypotension in experimental models of endotoxemia is mediated by PAF.¹⁸⁹ PAF infusion leads to a shock state that is similar to septic shock in that there is tissue hypoperfusion despite adequate fluid resuscitation. In animal studies, PAF has been shown to contribute many manifestations of sepsis including coronary vasoconstriction, reduced cardiac contractility, reduced preload, peripheral vasodilation, pulmonary vasoconstriction, increased microvascular permeability, gastrointestinal hemorrhage, and thrombocytopenia.¹⁸⁰ Two prospective randomized, placebo-controlled trials of PAF inhibition in sepsis have suggested a benefit.¹⁸⁰

PAF acetylhydrolase, an enzyme regulated by dexamethasone, estrogen, and PAF itself, is the enzyme responsible for degradation of PAF.

FIGURE 6.10. Kinin pathway. (Modified from Proud D, Kaplan AP. Kinin formation: mechanisms and role in inflammatory disorders. *Annu Rev Immun* 1988;6:49.)

Kinins

Kinins (i.e., bradykinin and lysyl bradykinin) are small vasoactive peptides generated during the inflammatory response (Fig. 6.10). Three mechanisms of kinin formation are operant during inflammation: (a) plasma proteins, (b) tissue proteins, and (c) cellular proteinases.^{190–193}

Production of Bradykinin. Biosynthesis commences with the activation of Hageman factor (HF), or factor XII of the coagulation cascade (Fig. 6.10). HF is activated by exposure to anionic surfaces such as the basement membrane of injured endothelium, heparin, or lipid A of endotoxin. It can also be proteolytically cleaved and activated by kallikrein. Prekallikrein circulates complexed with HMWK, a nonenzymatic protein. Kininogen enhances the binding of prekallikrein to negatively charged surfaces. Activated HF converts prekallikrein to kallikrein, which in turn activates more HF in a positive feedback cycle. HF_a, a cleavage product of activated HF, is also capable of activating prekallikrein. Kallikrein in plasma, tissues, and secretions specifically cleaves HMWK to release the nonapeptide bradykinin. In addition to bradykinin production, kallikrein participates in the activation of plasminogen and C1q of the complement system, yet another link between inflammation and the coagulation system. The only major plasma inhibitor of activated HF is C1 inhibitor. The primary inhibitors of kallikrein in plasma are C1 inhibitor and α_1 -macroglobulin.^{39,190}

Kinin Production in Tissue. Lysyl-bradykinin (kallidin) is the cleavage product of either HMWK or low-molecular-weight kininogen (LMWK) by tissue kallikreins, which are proteins distinct from their plasma counterparts. LMWK is present in higher concentrations intracellularly compared with HMWK. Whereas both HMWK and LMWK can be converted to lysyl-bradykinin by tissue kallikrein, only HMWK is cleaved by plasma kallikrein. Kallidin itself can be converted to bradykinin by a plasma aminopeptidase. Both kallidin and bradykinin use the same receptors and perform similar functions, but kallidin is approximately 85% as potent as bradykinin. Tissue kallikrein is synthesized from a preproenzyme and is converted intracellularly to tissue prokallikrein by enzymes that are not yet well

characterized. The secreted prokallikrein is then converted to tissue kallikrein extracellularly by plasmin or plasma kallikrein. The only significant inhibitor of tissue kallikreins is α_1 -proteinase inhibitor.^{39,190}

Cellular Kininogenase Activity. Neutrophils, mast cells, and basophils are sources of kininogenase activity. Neutrophils produce leukokinins by way of cathepsin D. Their role in inflammation is unclear. Bradykinin is metabolized sequentially to the partially active eight-amino-acid peptide, des-Arg-bradykinin, by carboxypeptidase N, and then to inactive 5-amino-acid and three-amino-acid fragments by the angiotensin-converting enzyme (ACE). ACE is the predominant enzyme to inactivate bradykinin in the pulmonary vasculature. Arginine released as a byproduct of the carboxypeptidase N reaction may contribute further to the modulation of inflammation by acting as a substrate for the formation of NO.^{39,190,194}

There are three kinin receptors, of which two are well characterized.^{190,192} B1 receptors are expressed primarily on the vasculature under pathologic conditions such as tissue injury. They bind des-Arg-bradykinin and des-Arg-kallidin and may mediate the hypotension characteristic of sepsis as well as pain.^{190,195} Both B1 and the more widely distributed B2 receptors are G-protein-coupled receptors. Activation of B2 receptors stimulates IP and phospholipase C (PLC), resulting in the accumulation of the second messengers IP₃, DAG, and calcium. The B2 receptors are more important in mediating the effects of inflammatory kinins, such as bradykinin and lysyl-bradykinin. These kinins induce arteriolar dilatation and mediate pain. Similar to histamine, bradykinin increases the gaps between postcapillary venule endothelial cells to increase vascular permeability. It is a potent constrictor of bronchial, uterine, and gastrointestinal smooth muscle, as well as the coronary and pulmonary vasculature.¹⁹² Activation of endothelial B2 receptors stimulates production of NO to further enhance vasodilatation. Kinins have been implicated in mediating the antihypertensive and cardioprotective effects of ACE inhibitors.¹⁹⁶ ACE, in addition to catalyzing the formation of angiotensin II from angiotensin I, promotes the hydrolysis of bradykinin to inactive metabolites. In addition, bradykinin can modulate platelet function by stimulating endothelial cell secretion of PGI₂ and thromboxane through activation of PLA₂.¹⁹⁰

Neuropeptides

Neuropeptides may provide the neuroendocrine link between psychological stress and inflammatory diseases such as psoriasis and inflammatory bowel disease. Like cytokines, their actions are pleiotropic and redundant. Neuropeptides execute their inflammatory and immunomodulatory effect by binding to specific G-protein–coupled receptors on the surfaces of target cells, and the resultant effect may be proinflammatory, anti-inflammatory, or both. For example, substance P mediates the hypothalamic fever response to PGE₂ induced by IL-1 and TNF- α , whereas adrenocorticotrophic hormone (ACTH), arginine vasopressin (AVP), and α -melanocyte-stimulating hormone (α -MSH) suppress it. The pituitary peptides prolactin, corticotropin-releasing hormone (CRH), and AVP have been shown to augment immune responses by enhancing T_H1 activity.^{39,197,198}

Tachykinins are important proinflammatory neuropeptides that mediate pain and vasodilatation and promote the classic inflammatory signs of erythema and edema. Substance P stimulates monocyte and neutrophil influx and neutrophil phagocytosis. Its inflammatory effects appear to be mediated by the proinflammatory cytokines TNF- α and IL-1 from mast cells, monocytes, macrophages, bone marrow, and endothelial cells. During allergic inflammation, substance P stimulates histamine release from mast cells. As an effector of immune function, substance P promotes T-cell proliferation and antibody production. Substance P released locally by nerve terminals is important in mediating the perception of pain.^{39,190}

CRH induces the release of IL-1, IL-6, and superoxide anion from macrophages and regulates its own proinflammatory effects through cortisol release. Cortisol downregulates production of proinflammatory cytokines such as IL-1, TNF- α , and IL-2; metalloproteinases; and inducible nitric oxide synthase (iNOS), and through this negative feedback loop, inhibits the production of CRH as well as ACTH and AVP. AVP, growth hormone, and prolactin are other important proinflammatory neuropeptides.^{39,197,198}

Vasoactive intestinal peptide (VIP) and its homologues display both proinflammatory and anti-inflammatory effects. VIP is widely distributed throughout the central and peripheral nervous systems and serves as a chemoattractant for macrophages, neutrophils, and T cells, and may play an important role in granulomatous reactions. VIP stimulates the release of histamine, and IL-5 and is a potent vasodilator. It inhibits IL-6, TNF- α , and IL-12 release and iNOS expression in activated macrophages. VIP has also been shown to stimulate the production of the anti-inflammatory cytokine IL-10 by macrophages and inhibit T-lymphocyte proliferation and IL-2 and IFN- γ production.¹⁹⁹

Somatostatin and α -MSH are primarily anti-inflammatory in action. Somatostatin, which colocalizes with substance P in sensory nerves, inhibits IgE formation and NK cell activity. α -MSH inhibits leukocyte chemotaxis and IFN- γ production and downregulates T_H1 activity. ACTH, calcitonin, and β -endorphin are other neuropeptides with predominantly anti-inflammatory properties.³⁹

Calcitonin gene-related peptide (CGRP) is an immunomodulator that inhibits the activity of T cells and macrophages, in part through the induction of IL-10. It also is an inhibitor of antigen presentation. CGRP promotes vasodilatation and neutrophil influx and synergizes with bradykinin and histamine to promote edema formation.

Nitric Oxide. The endogenous synthesis of NO was first identified in 1987, and NO was the first gaseous molecule shown to be synthesized for the purpose of cell signaling.²⁰⁰ NO is a weakly reactive radical that diffuses short distances from cell to cell independent of membrane channels or receptors. Its half-life is short because of its rapid inactivation by

hemoglobin and other endogenous substances; thus, it functions primarily in a paracrine and autocrine fashion. The enzyme NO synthase (NOS) catalyzes the formation of NO and citrulline from the substrates L-arginine and oxygen.^{50,201–203} NOS contains prosthetic groups for flavin-adenine dinucleotide, flavin mononucleotide, tetrahydrobiopterin, iron protoporphyrin IX, and zinc. Three isoforms of NOS have been identified. The calcium-dependent constitutive isoforms, neuronal NOS (nNOS) and endothelial NOS (eNOS), generate the small amounts of NO necessary for those processes maintaining physiologic homeostasis, such as neurotransmission and endothelial regulation of vascular tone. The expression of iNOS, however, requires stimulation and produces larger, sustained amounts of NO with both cytoprotective and cytotoxic properties. This distinction is not absolute, as certain cell populations express low basal levels of iNOS, and constitutive NOS transcripts can be enhanced by certain stimuli such as shear stress and hypoxia.^{50,201–203}

Many of the physiologic effects of NO are mediated by the activation of soluble guanylate cyclase. Increased levels of intracellular cyclic guanosine monophosphate trigger a reduction in calcium concentration and promote vascular smooth muscle relaxation and the inhibition of platelet aggregation and adhesion. The cellular response to NO also likely involves multiple signal transduction mechanisms including the MAPK pathway.

Inflammation secondary to endotoxemia, hemorrhagic shock, and ischemia/reperfusion are associated with increased NO production by iNOS. iNOS, first described in macrophages, can be expressed in essentially any cell type in response to immunologic stimuli, and unlike nNOS and eNOS, does not depend on elevations in intracellular calcium levels for its activity.^{50,201–203} Important activators of iNOS upregulation include LPS, IL-1, TNF- α , and IFN- γ . Expression is primarily transcriptionally regulated, although stabilization of iNOS mRNA also appears to play a role. IFN- γ stabilizes iNOS mRNA, whereas TGF- β can destabilize it. Transcription of the iNOS gene is controlled by NF- κ B, IFN- γ -responsive element, and TNF-responsive element. Induction of iNOS can be inhibited by glucocorticoids, thrombin, macrophage deactivation factor, PDGF, IL-4, IL-8, IL-10, and IL-13.^{50,201–203} Dexamethasone may inhibit iNOS induction by impairing the DNA-binding capacity of NF- κ B and by increasing levels of I- κ B.^{204,205}

The endothelial dysfunction and vascular hyporeactivity characteristic of septic shock is mediated in part by iNOS production of NO.²⁰⁶ NO has been shown to be the effective mediator of the negative myocardial inotropy of TNF- α , IL-6, and IL-2 and the TNF- α -induced vasodilatation in the systemic and microcirculations.²⁰⁷ NO may indirectly increase prostaglandin production by increasing the catalytic activity of cyclooxygenase and decrease leukotriene production by inhibiting 5-lipoxygenase.²⁰⁸ NO plays an autoregulatory role in the T_H1 subset of T_H cells by limiting their own proliferation.²⁰⁹

NO can mediate tissue injury in inflammation by modulating organ perfusion, mediating interactions with neutrophils, contributing to proinflammatory signaling, and regulating apoptosis.²¹⁰ Whereas eNOS primarily regulates perfusion during homeostasis, both eNOS and iNOS modulate organ flow in pathophysiologic states. Basal NO production from eNOS prevents the adherence of neutrophils to the endothelium and inhibits chemotaxis under physiologic conditions. Animal studies have demonstrated that pharmacologic inhibition of iNOS or genetic deletion of iNOS attenuates neutrophil accumulation in organs after ischemia/reperfusion injury.²¹¹ Conversely, similar experiments in endotoxemia implicate an antiadhesive role for iNOS, suggesting that the effect of induced NO on neutrophil accumulation is insult specific.²¹⁰ Activated neutrophils can be stimulated by fMLP, PAF, and LTB₄ to produce NO. NO produced by neutrophils at sites of

inflammation can combine with superoxide to form peroxynitrite as another means of effecting toxicity.^{39,212}

The reaction of NO with superoxide is the only reaction that outcompetes the reaction of superoxide with superoxide dismutase. Although small amounts of peroxynitrite are produced under basal conditions from constitutively produced NO and superoxide from mitochondria and other cellular sources, endogenous antioxidants such as GSH, vitamins E and C, and superoxide dismutase likely limit its toxicity. A low concentration of peroxynitrite has been shown to inhibit neutrophil adhesion. Higher concentrations of peroxynitrite can initiate a wide range of toxic oxidative reactions through a peroxynitrous acid intermediate. These include the initiation of tyrosine nitration, lipid peroxidation, and direct inhibition of mitochondrial respiratory enzymes. The balance between superoxide and NO determines the reactivity of peroxynitrite; excess NO reduces the oxidation elicited by peroxynitrite. In addition, peroxynitrite may contribute to cytotoxicity by a more indirect pathway. Peroxynitrite-induced single-strand breaks in DNA activate the nuclear enzyme poly(ADP-ribose) synthetase, leading eventually to irreversible energy depletion of the cells and necrotic-type cell death.^{39,41}

Inducible NOS plays a key role in host defense, with NO or peroxynitrite exhibiting potent antimicrobial activity against a number of pathogens including viruses, fungi, and bacteria. Although microbicidal susceptibility to NO-mediated killing can vary considerably between species, essential roles have been identified in tuberculosis and bacterial peritonitis.²¹³ Induced NO has been shown to be essential for the upregulation of the inflammatory response in hemorrhagic shock and is likely to be so in other inflammatory processes. NO produced by iNOS leads to the activation of NF- κ B.²¹⁴ This is followed by the induction of proinflammatory cytokines and increased leukocyte recruitment and activation.

NO has demonstrated both proapoptotic and antiapoptotic effects depending on the circumstances. NO derived from eNOS may inhibit apoptosis.²¹⁵ Proapoptotic effects appear to be associated with pathophysiologic conditions in which iNOS is upregulated. Low concentrations of peroxynitrite have also been shown to induce apoptosis, whereas higher concentrations promote cell necrosis in vitro. The role of NO-mediated apoptosis in the regulation of the inflammatory response has yet to be more clearly defined.

In summary, NO mediates tissue injury both directly through the formation of peroxynitrite and indirectly through the amplification of the inflammatory process. Like many mediators, however, NO has dual regulatory functions and is therefore difficult to characterize as either proinflammatory or anti-inflammatory. In general, basal levels of NO produced by constitutive NOS may confer anti-inflammatory effects, whereas induced NO may tend to promote the upregulation of the inflammatory response. It is likely that an optimal level of NO is necessary in host defense; too little NO may be as harmful as too much.

Heme Oxygenase

Heme oxygenase catalyzes the breakdown of heme to iron, biliverdin, and carbon monoxide (CO).²¹⁶ Three isoforms of HO have been identified. HO-2 is constitutively expressed in many tissues, whereas HO-3 expression appears to be limited to the brain. HO-1 is not expressed constitutively in most tissues, but is rapidly upregulated by both heme and nonheme cellular stresses, including hypoxia, redox stress, and inflammation. Additionally, NO is a potent inducer of HO-1. HO-1 has profound antiapoptotic and anti-inflammatory effects. These cytoprotective effects have been attributed to the individual catalytic products of heme metabolism. Biliverdin is converted to bilirubin by biliverdin reductase, and bilirubin has been demonstrated to act as a potent intracellular antioxi-

dant. Carbon monoxide alone can mimic many of the actions of HO-1 and has been shown to protect in models of sepsis, hemorrhagic shock, and ischemia/reperfusion when administered as an inhaled gas. The mechanisms of action of carbon monoxide have both similarities and dissimilarities with nitric oxide and are an area of active investigation.²¹⁶

Hydrogen Sulfide

Hydrogen sulfide (H₂S) is a colorless, flammable gas, with the typical malodor of putrid eggs. It is highly lipophilic and freely penetrates the cell wall, which greatly facilitates its biologic activity.²¹⁷ Recent evidence highlights the widespread distribution of H₂S in the plasma, brain, and other tissues. H₂S is formed in mammalian cells largely by the activity of two pyridoxal phosphate-dependent enzymes, cystathione γ -lyase (CSE) and cystathionine β -synthetase (CBS), that utilize cysteine and homocysteine to form H₂S.²¹⁷ Large amounts of these enzymes occur in the brain (CBS), liver (CSE), kidney (CSE), and blood vessels (CSE). Interestingly, lipopolysaccharide exposure induces the expression of CSE, suggesting that H₂S may regulate inflammation.²¹⁸ Both pro- and anti-inflammatory actions have been described. H₂S levels and CSE expression are increased in animal models of endotoxemia, sepsis, and hemorrhagic shock.^{218–220} It has been shown to increase leukocyte attachment and rolling in jejunal blood vessels and to increase ICAM-1 expression.²²¹ In human monocytes, H₂S donors induced the formation of proinflammatory cytokines and chemokines via a NF- κ B mechanism.²²² Inhibitors of CSE reduced the inflammation in these animal models of sepsis and hemorrhage. By contrast, H₂S decreased LPS-induced upregulation of NF- κ B in RAW 264.7 macrophages, and H₂S-releasing derivatives of diclofenac exhibited greater anti-inflammatory activity in endotoxic shock.^{217,223,224}

RECOGNITION AND ACTIVATION PROCESSES

Exogenous and Endogenous Danger Recognition

Multicellular organisms have evolved an essential mechanism of surveillance, defense, and repair of injured cells. Implicit with this system is the ability to differentiate pathogens and damaged cells from self. The initial response is orchestrated by the evolutionarily ancient and more universal innate immune system, which employs monoclonal sets of recognition molecules called pattern recognition receptors (PRRs).^{225,226} PRRs bind conserved molecular structures found in large groups of pathogens, termed PAMPs. PAMPs are a diverse set of microbial molecules, which share a number of different recognizable biochemical features that alert the organism to intruding pathogens.^{225–227} These PAMPs are recognized by cells of innate and acquired immunity, primarily through the Toll-like PRRs. Activation induces several signaling pathways, most notably NF- κ B.^{225,227} Consequent to this activation, an immune response is triggered to destroy the pathogen and/or pathogen-infected cells, and an adaptive response is initiated to select pathogen-specific T cells and antibodies for future occasions.

However, pathogens are not the only causative agents of tissue and cell damage. Cells, and thus tissues, can be injured by various noxious insults: heat, cold, chemicals, radiation, ischemia, or direct mechanical injuries. Evolution has enabled us to deal with these damages, which though not caused by pathogens, still necessitate repair. It is becoming apparent that specific receptors exist by which to recognize extrinsic threats (i.e., pathogen) and intrinsic altered self (cytokines, oxidized mitochondrial DNA, heat-shock proteins, and uric acid).²²⁷

Danger-associated Molecular Patterns

9 DAMPs, the endogenous equivalent of PAMPs, represent danger signals or “alarmins” and share many characteristics similar to cytokines.²²⁷ DAMPs may be released following nonprogrammed cell death, such as necrosis, and under such circumstances tend to elicit inflammation. By contrast, programmed cell death (i.e., apoptosis) incorporates mechanisms such as acetylation to minimize the release of these mediators and any subsequent inflammatory response. Cells of the immune system also can be induced to secrete these mediators.²²⁷ This secretion may occur by specialized secretion systems or by the classical ER-Golgi secretion pathway.²²⁷ Under these circumstances, DAMPs may facilitate the inflammatory response by aiding the recruitment of innate immune cells, most notably dendritic cells. In doing so, they indirectly orchestrate the subsequent adaptive immune response and facilitate tissue repair.²²⁷ The prototypical alarmin, HMGB1, has already been discussed. Here we briefly discuss mediators recently added to this list.

S100 Proteins. The family of S100 proteins incorporates over 20 related calcium-binding proteins.²²⁷ S100A8 and S100A9 form heterocomplexes in the cytosol of granulocytes, monocytes, and macrophages, whereas S100A12 exists as homodimers in the cytoplasm of granulocytes. S100 proteins are actively secreted at sites of inflammation via a nonclassical pathway. The receptors mediating their effects are still being defined, though it appears that S100A12 and S100B interact with RAGE, whereas S100A8/9 may interact with TLR receptors. S100 proteins have been shown to induce increased vascular permeability and a prothrombotic effect. Recent studies implicate S100 proteins in the pathogenesis of autoimmune arthritis and psoriasis.²²⁷

Uric Acid. Uric acid is released after cellular injury, and upon exposure to the extracellular environment, precipitates to form monosodium urate (MSU).²²⁷ Uric acid stimulates dendritic maturation and, when coinjected with antigen *in vivo*, significantly enhances the generation of responses from CD8⁺ T cells.²²⁷ It has significant proinflammatory properties that are best evidenced in the disease gout, in which uric acid accumulates in tissues and induces inflammation-dependent arthritis. MSU crystals engage the inflammasome, resulting in the production of IL-1 β and IL-18.²²⁷ Macrophages from mice deficient in IL-1R or in various components of the inflammasome, such as caspase-1, ASC, and NaLP3, are defective in MSU-induced cytokine secretion and have reduced inflammation.²²⁷ Extracellular uric acid is eliminated by uricase.²²⁷

Receptors for Danger Recognition. Innate immunity is not antigen specific, but rather programmed to respond to groups of evolutionarily conserved macromolecules that represent “patterns of danger” and signal a potential threat to the host. PRRs identify these PAMPs and include the Toll-like receptors and NOD-like receptors. Recent studies highlight the promiscuity of these PRRs in also recognizing and mediating DAMP-dependent signaling. In fact, multiple positive feedback loops between DAMPs and PAMPs and their overlapping receptors may represent the molecular basis for the observation that infections, as well as nonspecific stress factors, can trigger flares of autoimmune diseases (i.e., rheumatic).¹⁴⁷ Additional novel receptors have subsequently been identified and designated PRRs, including RAGE.^{226,227}

CD14. The prototypical receptor identifying external infectious threats (i.e., gram-negative infections) is CD14. CD14 was identified as the LPS receptor when transfection of CD14-negative CHO cells with CD14 conferred responsiveness to LPS.²²⁸ Its critical role in LPS recognition is underscored by the LPS-hyporesponsive phenotype of CD14-deficient mice. It has

been identified on cells of the myeloid lineage, B cells, liver parenchymal cells, and fibroblasts. Differential expression is observed, ranging from high levels on peritoneal and pleural macrophages to lower levels on Kupffer cells, alveolar macrophages, monocytes, and PMNs. Expression may be modified as human PMNs express low levels of CD14 that is upregulated by TNF- α , G-CSF, GM-CSF, and fMLP. Prototypically, CD14 binds LPS bound to LPS-binding protein (LBP) in combination with MD-2 and presents it to TLR4.²²⁸ MD-2 is required for cellular responsiveness to LPS, as demonstrated by both transfection studies and an analysis of a CHO cell line with a mutated MD-2 gene. Most of the available evidence indicates that a complex of TLR4/MD-2/CD14 directly binds LPS.²²⁸ CD14 is also important in TLR2 signaling, whereby it presents bacterial products other than LPS.

Toll-like Receptors. CD14 is a glycosylphosphatidylinositol-linked receptor devoid of any transmembrane domain. This, in combination with the identification of a soluble form of CD14, necessitated identifying the manner by which LPS induced activation.²²⁹ In 1996, the Toll protein in *Drosophila* was shown to be necessary for an effective immune response to the fungus *Aspergillus fumigatus*.²²⁵ In 1998, Poltorak et al. discovered that the *lps* gene in LPS-hyporesponsive C3H/HEJ mice encoded a murine member of the TLR family. These data provided the initial evidence that mammalian TLRs function as PRRs.²³⁰ Subsequent studies have confirmed that TLR4 is the “LPS receptor” and that it is essential for the defense against gram-negative microorganisms.²²⁸

Thirteen mammalian TLR receptors have been characterized. Each recognizes a specific set of conserved microbial molecules, and as a family, they can detect most microbes.²²⁸ Interestingly, the subcellular localization of different TLRs correlates to some extent with the molecular patterns of their ligands and their function.²³¹ TLR1, TLR2, and TLR4 are located on the cell surface and are recruited to phagosomes after activation by their respective ligands. They are the receptors mediating the response to exogenous insults including bacterial infection and trauma. By contrast, TLR3, TLR7, and TLR9, all of which are involved in the recognition of nucleic acid-like structures (i.e., viral DNA), are expressed intracellularly.^{225,232}

TLR4 is required for the innate response to gram-negative organisms and LPS, though other TLRs, such as TLR2, can also recognize and mediate this response.²²⁶ TLR4 has been shown to trigger the response to additional ligands, including lipoteichoic acid (LTA) and peptidoglycans from gram-positive bacteria and the fusion protein of the respiratory syncytial virus.²³³ Individuals with the D299G polymorphism in TLR4 demonstrate increased risk of gram-negative infections, and other studies have linked this with an increased incidence of SIRS.²³⁴ In addition, this polymorphism has been associated with alterations in the susceptibility to other inflammatory and potentially infectious processes (carotid artery atherosclerosis, coronary artery disease).²³⁴ Heat-shock protein 60 (HSP60) of chlamydial origin has been found in atherosclerotic plaques and can bind TLR4. Perhaps recognition of HSP60 by human TLR4 might exacerbate the inflammatory component of atherosclerosis, whereas people with the D299G polymorphism might be at least partly protected from this exacerbation.²³⁴ TLR4 has been well characterized as a PRR for DAMPs, including heat-shock proteins (HSP60, HSP70, Gp96), hyaluronate, heparan sulfate, and other matrix proteins. Because of its ability to recognize endogenous proteins, TLR4 is implicated in a variety of diseases, including arthritis and atherosclerosis.^{147,232}

TLR2 recognizes lipoproteins derived from the cell wall of bacteria such as *Treponema pallidum* and *Mycoplasma fermentans*, LTA from gram-positive bacteria, lipopeptides, LPS, and lipid A.^{226,232,233} It also can recognize a host of DAMPs, including the heat-shock proteins, fibronectin, fibrinogen, heparan sulfate, and hyaluronate. Recent data suggest that TLR2 forms heterodimers with other TLRs, including TLR1

or TLR6, to recognize these DAMPs. A likely consequence of this cooperation is an increased repertoire of ligand specificities. The R753Q polymorphism in the TLR2 is associated with a decreased response to these bacteria and may increase susceptibility to staphylococcal infections or tuberculosis.^{232,234}

Additional TLRs involved in inflammation include TLR9, which recognizes unmethylated CpG motifs present in bacterial DNA. By contrast, most of the host mammalian genome is methylated. TLR9-ligand engagement occurs intracellularly, in either endosomes or lysosomes, presumably following bacterial lysis. Recent evidence suggests that TLR9 can identify host DNA released by dead or dying cells, and hence may be involved in the autoimmune diseases such as systemic lupus erythematosus (SLE).²²⁵ TLR5 recognizes flagellin of bacterial flagella.²³² TLR3 recognizes double-stranded RNA of both viral and endogenous sources. Because of the latter characteristic, TLR3 has been implicated in autoimmune arthritis.

TLRs induce signal transduction via their cytoplasmic Toll-interleukin-1 receptor (TIR) domains to promote the expression of a variety of host defense genes. These include inflammatory cytokines and chemokines, antimicrobial peptides, costimulatory molecules, MHC molecules, and other effectors. A considerable portion of the functional response is mediated by activating intracellular signaling pathways that culminate in the induction of the transcription factor NF- κ B. Specifically, the CD14/MD-2/TLR4 complex, upon engagement with LPS-LBP, recruits the adapter protein MyD88, which subsequently engages the serine/threonine kinase IRAK. IRAK undergoes autophosphorylation and recruits TRAF6. Ultimately, activated IRAK phosphorylates and targets for degradation the NF- κ B inhibitor I- κ B, which enables the nuclear translocation of NF- κ B and transcription of inflammatory genes. AP-1 and members of the MAPK transduction cascade are also activated by this mechanism. This pathway is critical to the production of IL-12, TNF- α , and IL-6. All TLRs signal through this conserved signaling cascade, and for some, MyD88 (TLRs 2, 6, 9) is their sole receptor-proximal adaptor. For instance, MyD88 is essential for clearance of *S. aureus*, a gram-positive bacteria, which would signal through TLRs 2, 6, 9.^{225,226,233}

Subsequent studies utilizing MyD88-deficient mice suggested that alternate TLR pathways existed. These mice, in response to many TLR ligands, including peptidoglycan and unmethylated CpG motifs, did not activate NF- κ B or MAPK. Surprisingly, however, LPS could still activate NF- κ B and MAPK, though in a delayed fashion. Subsequently, a MyD88-independent pathway has been characterized that is utilized by TLR4 and utilizes a distinct adaptor protein called TIR domain-containing adaptor protein (TIRAP) or Mal. A dominant negative mutant of TIRAP specifically impairs TLR4- and TLR2- but not IL-1R- or TLR9-induced NF- κ B, indicating a specificity of TIRAP for the TLR4 pathway. A third TIR-containing adaptor molecule, TIR domain-containing adaptor inducing IFN- β (TRIF), also appears to mediate an MyD88-independent pathway.^{225,226,233}

Most of this research has occurred in the realm of sepsis and provided insight into the manner by which organisms identify infectious threats and activate the inflammatory pathway to preserve the host. However, several circumstances of sterile inflammation suggest a role of the TLRs in mediating inflammation in response to endogenous danger signals (uric acid, mitochondrial DNA, HMGB1).²²⁸ Hepatocellular injury consequent to ischemia/reperfusion (I/R) has been shown to be dependent on TLR4.³²

RAGE. RAGE is an immunoglobulin superfamily molecule that belongs to the multiligand receptors that recognize families of ligands rather than a single polypeptide.^{95,227,235,236} It has a single transmembrane spanning domain and a highly charged cytoplasmic tail that, though lacking known signaling motifs, is critical for cellular activation. Though RAGE knockout mice

are viable and fertile, they display a wide range of defects. Most of these defects are subtler than expected, leading to the suggestion that other receptors with overlapping function might exist. Signaling appears to necessitate clustering into a particular orientation, which facilitates binding of cytosolic signaling complexes.^{95,235} Its ligands include products of nonenzymatic glycosylation (e.g., advanced glycation end-products or AGEs), the amyloid- β precursor protein, the S100/calgranulin family of proinflammatory cytokinelike mediators, and HMGB1, and its expression is upregulated at sites of diverse pathologies including atherosclerosis and Alzheimer disease. In fact, RAGE-mediated cellular stimulation is thought to increase expression of the receptor itself, thereby generating a positive feedback mechanism and perpetuating the proinflammatory state.^{95,235,236}

Recent studies demonstrate the activation of multiple signal transduction cascades subsequent to ligand binding, including the MAPK family (p38, ERK1/2, and JNK) and Rho GTPases (cdc42 and rac).²³⁶ Like TLRs and IL-1R, RAGE engagement leads to NF- κ B activation, suggesting that both receptor usage and signaling pathways evoke similar responses when cells are activated by PAMPs and DAMPs. It is currently hypothesized that RAGE-ligand interaction induces a new heightened basal state of activation. With a superimposed stimulus, cellular perturbation is magnified. Rather than returning to homeostasis, cellular signal transduction mechanisms favor augmented dysfunction.^{95,235}

Studies have implicated RAGE to be an important receptor during various acute and chronic inflammatory processes as well as tumor biology. RAGE expression and function directly correlated with tumor growth in RAGE-transfected C6 glioma cells. In a murine tumor model, in mice treated with soluble RAGE, which functions as a decoy, there was a reduction in lung metastases, cellular invasion, and expression of matrix metalloproteinases.²³⁶

RAGE has also been identified as a receptor for S100A12, a member of the S100/calgranulin family of proinflammatory mediators. Endothelial cells cultured with S100A12 displayed RAGE-dependent expression of VCAM-1 and tissue factor. Mononuclear phagocytes displayed S100A12-RAGE chemotaxis, expression of tissue factor, and elaborated IL-1 and TNF- α . In vivo studies of delayed-type hypersensitivity demonstrated reduced inflammatory response when mice were treated with anti-RAGE F(ab')₂, anti-S100 F(ab')₂, or soluble RAGE. Treated animals also displayed reduced NF- κ B activation and IL-1 and TNF- α expression.²³⁶

The angiopathy of diabetes is thought to be consequent to inflammatory processes generated by elevated glucose concentrations. Hyperglycemia has been demonstrated to activate numerous signaling cascades. One process that might mediate these effects is through the nonenzymatic formation of AGEs.^{95,235,236} AGE-RAGE interactions on endothelium lead to the expression of procoagulant tissue factor and VCAM-1 and macrophage-released tissue factor. Animals treated with soluble RAGE showed decreases in atherosclerotic lesion area and number and a marked reduction in lesion complexity. Also, treated animals had reduced expression of adhesion molecules, tissue factor, MCP-1, and matrix metalloproteinases.^{95,235,236}

CD91

The immunologic properties of HSPs were discovered by their ability to elicit antitumor immunity. It was later discovered that this antigenic specificity was determined by the peptides they chaperoned. APCs can bind and internalize HSP-peptide complexes derived from virus-infected cells or tumors and represent them on MHC class I molecules. In addition, APC engagement of HSP-peptide complexes induces maturation, the expression of costimulatory molecules, and the induction and release of cytokines (TNF- α , IL-1, IL-12, IL-6, GM-CSF, MIP-1, RANTES, and NO).^{237,238}

CD91 had been identified as a receptor for the serum protein α_2 -macroglobulin, a natural protease inhibitor that, like HSPs, is found across many species. In fact, α_2 -macroglobulin is the evolutionary precursor of the C3 complement component. By binding pathogen proteases utilized during invasion and shuttling them for endocytosis, α_2 -macroglobulin hinders pathogen invasion.^{237,239}

However, such a method of host defense would be ineffective for intracellular pathogens that gain access by alternative means, such as mimicking host proteins and developing ligands for host receptors. Hence, another method of signaling danger is necessary. It is currently thought that upon cell death, HSPs contained within the cell transfer information regarding the infected intracellular environment to CD91. This large cell surface receptor, complexed with the HSPs, is internalized and delivers antigen into the classical MHC class I pathway. The MHCs bind and present them to CD8⁺ T cells. On recognizing nonself, T cells are induced to proliferate and mediate killing. This mechanism could be generalized to implicate CD91 and HSP interactions in the recognition of all cellular stress that culminates in injury and death.²³⁹

CD91 was first identified by Binder et al. as the receptor for Gp96 and then by Basu et al. as a common receptor for other HSPs (HSP70, HSP90, and calreticulin).^{240,241} This large multidomain 600-kD protein possesses multiple binding sites for at least 32 ligands. The binding of this receptor to many members of the HSP family has been corroborated by several independent functional and structural studies.²³⁹

Several *in vivo* studies suggest a physiologic relevance for HSP-CD91 interaction. Mice immunized with tumor-derived Gp96-peptide complexes reject a subsequent tumor challenge. If CD91 antiserum is mixed with the HSP-peptide inoculum, the mice fail to reject the tumors. Binder et al. noted that blocking of CD91 completely inhibits the phenomenon of re-presentation of peptides that are carried or chaperoned by HSPs, suggesting that not only is CD91 a receptor for HSPs, but it may also be the sole receptor involved in antigen re-presenting.^{238,241}

HSPs have been shown to chaperone antigenic peptides (tumor, viral, minor histocompatibility antigens) from all cellular compartments. The HSPs thus appear to be a universal mechanism for antigen capture, and they permit a high-efficiency antigen uptake through a receptor-mediated mechanism.

Evidence that HSP-peptide-CD91 interactions serve to signal cellular stress is beginning to culminate. Basu et al. demonstrated that HSP70, HSP90, Gp96, and calreticulin are released from cells as a result of necrotic cell death, but not apoptotic cell death.²⁴⁰ Similarly, Melcher et al. reported that tumor cells undergoing necrotic death are highly immunogenic as compared to those undergoing apoptotic death.²⁴² Actual necrosis may be unnecessary as stressed cells and cancer cells have been reported to express cell surface HSP molecules, which may activate APCs. Zheng et al. observed that physical contact of tumor cells artificially engineered to express cell surface HSPs with immature DCs elicits a powerful maturation of DCs.²⁴³

Other Heat Shock Protein Receptors. CD40 was reported as a receptor for HSP70 when anti-CD40 antibodies were observed to inhibit macrophage chemokine secretion in response to mycobacterial HSP70. Subsequently, Becker et al. noted the association of recombinant GST-tagged CD40 with murine HSP70.^{244,245} They further demonstrated enhanced binding after the APCs were stimulated with LPS. As LPS induces expression of a number of cell surface molecules, the authors concluded that CD40 mediates recognition and binding of HSP70.²⁴⁶

CD36 has been implicated as a receptor for Gp96. Transfection of CD36 into CD36-negative cells has been shown to enhance Gp96 binding. In addition, CD36^{-/-} macrophages have a 52% reduction in Gp96 binding compared with wild-type controls, suggesting some role for CD36 as an HSP receptor.²⁴⁶

LOX-1, a member of the same scavenger superfamily as CD91 and CD36, has been postulated to be an additional

receptor for endocytic uptake of HSP70 and chaperoned peptides by human DCs. Anti-LOX-1 antibodies and LOX-1 ligand-acetylated albumin competed with HSP70 for binding to DCs.¹¹³

Both TLRs and CD14 have been implicated as receptors for HSPs, such as HSP70.²⁴⁷ HSP70 stimulates macrophage IL-12p40 production that is partially abrogated by inhibiting downstream TLR signaling cascades. In addition, human HSP60 activated NF- κ B and TNF- α production by 293 T cells transfected with either TLR-2 or TLR-4 and MD-2.²⁴⁸ HSP60 also activated JNK and IKK signaling and TNF- α production by macrophages, an effect that was partially eliminated by knocking out MyD88 or TRAF6. Similar functional studies have proposed that CD14 might serve as an HSP70 receptor in APCs. All of these studies heavily suggest a role of TLRs or CD14 in HSP binding, although several investigators call into question the potential for contamination with LPS to be mediating much of these effects.²⁴⁶

The Stress Response

The stress response is the cellular reaction to any external perturbation or disruption in equilibrium and serves to restore homeostasis. It is often referred to as the heat-shock response after the identification in the 1960s of a group of genes expressed after exposure to heat, the heat-shock proteins (*supra vide*).²⁴⁹ However, subsequent investigations delineated additional cellular proteins that were expressed in response to a wide variety of insults. Inducers of the stress response include physical stresses (burns, radiation, trauma), chemical agents and mediators (toxins, heavy metals, cytokines, ROS), infectious agents (bacteria, viruses, parasites), and allergens. Clinically, expression of HSP has been observed under conditions in which oxygen delivery is compromised, as in hemorrhage or ischemia.²⁵⁰

Activation of the stress response is characterized by both morphologic and metabolic cellular alterations. Morphologic alterations include the accumulation of unprocessed forms of mRNA in the nucleolus and increased numbers of actin microfilaments in the cytoplasm. Changes in cellular metabolism include a rapid reduction in intracellular ATP levels, most likely correlated with alterations in the integrity of mitochondria. The stress response is characterized by transient downregulation of most cellular products and by the upregulation of stress proteins.²⁵¹ It is the induction of stress proteins that confers the primary adaptive and protective effects of the stress response. After expression of stress genes, cells become resistant to subsequent stresses. Members of the stress protein family include heme oxygenase (*supra vide*); the multiple-drug resistance gene product or P-glycoprotein, ubiquitin, involved in targeting proteins for degradation; scavengers such as superoxide dismutase, ferritin, and metallothioneins; and the glycolytic enzymes enolase and glyceraldehyde 3-phosphate dehydrogenase. The most extensively characterized are the HSPs.³⁹

Heat-shock proteins are molecular chaperones that may either be constitutively expressed or induced upon cellular stress.²⁵² Classification is based on their molecular mass and degree of homology. The most extensively studied is the HSP70 family, members of which possess a mean molecular mass of 70 kD and greater than 70% homology. Members of the HSP70 family bind ATP, and under conditions of energy depletion the stress response is induced. HSP70 is integral in cellular adaptation to and survival during environmental stresses. Both HSP72 and HSP73 are present in the cytosol and nucleus; the former is constitutively expressed, whereas expression of HSP72 is exclusively induced after stress. In most studies HSP72 is used as a marker of HSP induction.^{39,250,253,254}

The HSP60 family members are also referred to as chaperones. The glucose-regulated protein group of HSP is induced with glucose starvation, inhibitors of N-glycosylation, and calcium

ionophores. The decrease in glucose content may affect the pool of sugar donors during protein glycosylation. The low-molecular-weight HSPs (molecular masses of 20 to 30 kD) may be important regulatory components of the actin-based cytoskeleton.²⁵⁰

Transcription is mediated by the activation of heat-shock elements in the gene promoters. Two heat-shock transcriptional factors (HSFs) have been identified: HSF1 and HSF2. HSF1 activates transcription of the HSP72 gene in response to heat, heavy metals, and other inducers of the stress response. With stimulation, unbound HSF1 oligomerizes, translocates to the nucleus, and binds to the HSP promoter to activate the transcription of the gene. HSF2 is not activated by the classic inducers of heat-shock genes but may be important in controlling the activities of HSP gene expression in the normal or unstressed cell.^{39,250,253,254}

HSP can play multiple roles in modulating the inflammatory response. A number of inflammatory states such as rheumatoid arthritis, ARDS, and asthma have been shown to benefit experimentally from increased HSP expression.^{249–251,254} Functions of HSP during inflammation include enhancement of immune responses, thermotolerance, regulation of apoptosis, hemostasis, and cytoprotection against ROS and other inflammatory mediators. HSP-CD91 interaction is integral to the processing and representation of antigen by APCs. HSP may shift the balance between T_H1 and T_H2 toward an increase in more anti-inflammatory T_H2 cells. ROS, including H_2O_2 , hydroxyl radical, and peroxynitrite, activate HSP synthesis. In the presence of iron, ROS also induce the oxidation-specific stress protein heme oxygenase or ferritin, proteins contributing protection against oxidative stress by binding iron and preventing it from participating in the Fenton reaction. Mechanisms of HSP-mediated cytoprotection from the toxic effects of ROS include the maintenance of cellular GSH levels (HSP27) and mitochondrial protection (HSP70). Hence, ROS induce a cytoprotective response that counteracts their own toxicity. Other inflammatory mediators such as NO have also been shown to induce expression of HSP.³⁹

HSP may participate in intracellular signaling pathways that modulate the production or function of inflammatory mediators. For example, HSP90 has been shown to facilitate signaling that leads to NO formation by eNOS.²⁵⁵ HSP70 has been reported to prevent apoptosis, which may promote propagation rather than resolution of inflammation. In addition, the body's immune response to bacterial and parasitic stress proteins likely protects the host from infection. The bacterial homologue of HSP60, GroEL, is a major target of the mammalian humoral response to bacterial infections. Many activators of HSF1 are potent inhibitors of the proinflammatory transcription factor NF- κ B. Aspirin and other NSAIDs activate HSF while inhibiting NF- κ B. Therefore, the anti-inflammatory effects associated with the stress response might be related more to the inhibition of NF- κ B activation.^{250,256}

The Acute-phase Response

The acute-phase response consequent to trauma or cellular injury is characterized by alterations in hepatic metabolism; activation of the central nervous system, leading to fever and adaptive behaviors; altered hematopoiesis; activation of complement and the fibrinolytic and coagulation cascades; and the release of neuropeptides, kinins, and hormones. It is a rapid, nonspecific response that accompanies both acute and chronic inflammatory disorders. Many of the processes induced during the acute-phase response are mediated by cytokines; IL-6, IL-1, and TNF- α play particularly central roles.^{257,258} Though considered a defense mechanism promoting host survival, aberrant or unregulated production of many of these inflammatory mediators can be lethal.

Acute-phase Proteins. An acute-phase protein is defined as a protein whose concentration increases by at least 25% during

inflammation (Table 6.7).^{258,259} These changes are primarily due to altered hepatic synthesis, typically occur within approximately 6 hours of the inciting stimulus, and function to restore homeostasis. These functions include hemostatic functions (fibrinogen), microbicidal and phagocytic functions (complement components, C-reactive protein), antithrombotic properties (plasminogen, protein S), antioxidant properties (haptoglobin), and antiproteolytic actions (α_2 -macroglobulin, α_1 -protease, α_1 -chymotrypsin). The negative acute-phase proteins albumin, prealbumin, transferrin, and retinol-binding protein decrease by at least 25%. Levels of the negative acute-phase proteins albumin and transferrin drop almost immediately after operation and remain depressed for several days. The rapid initial loss of these proteins is likely due to increased vascular permeability and loss to the extravascular space. The magnitude of the response is proportional to the severity of the stress and is specific to the genetic composition of the patient. Whereas trauma and burns lead to significant increases in acute-phase reactants, exercise and psychiatric illness induce more moderate responses.

The two major acute-phase proteins in humans are C-reactive protein (CRP) and serum amyloid A (SAA). CRP, named because of its reaction with pneumococcal C-polysaccharide, displays both proinflammatory and anti-inflammatory effects. It has been shown to activate complement, recognize foreign pathogens, bind phagocytic cells, and enhance activation of tissue factor, the main initiator of coagulation. CRP can also inhibit superoxide production by neutrophils and inhibit neutrophil adhesion by decreasing surface expression of L-selectin. Changes in plasma or serum CRP, although nonspecific, may reflect the magnitude of an inflammatory process and may aid the differentiation of inflammatory from noninflammatory conditions. Measurement of CRP is more precise than the erythrocyte sedimentation rate (ESR), which largely depends on plasma fibrinogen levels and is influenced by a variety of other, unrelated factors in the circulation. SAA may affect cholesterol metabolism and promote chemotaxis and adhesion of phagocytes during inflammation.³⁹

C1 inhibitor is of special interest as an acute-phase protein because of its effects outside of the complement cascade. This antiprotease inhibits the activity of Hageman factor, limiting kinin production and factor XI production. Thus, enhanced expression of a complement inhibitor protein during the acute phase influences such diverse processes as the coagulation, fibrinolysis, and kinin pathways.

Systemic Manifestations of the Acute-phase Response.

Systemic manifestations include neuroendocrine changes, shifts in the hematologic profile, and metabolic and chemical alterations. The classic neuroendocrine manifestation is fever. IL-1, IL-6, and TNF- α mediate the fever response by resetting the hypothalamic temperature set point through the synthesis of PGE₂. The secretion of neuropeptides such as CRH and AVP and of hormones such as glucagon, insulin, thyroxine, and aldosterone is also characteristic of the acute-phase response. CRH and AVP released by the hypothalamus increase ACTH and cortisol levels. The rise in plasma cortisol levels occurs rapidly and may function to inhibit the fever response and cytokine gene expression, thereby serving a potential regulatory function in the acute-phase response. Glucocorticoids also stimulate macrocortin synthesis, which by inhibiting synthesis of PLA₂, limits the availability of arachidonic acid for prostaglandin synthesis. Glucocorticoids increase the rate of synthesis of certain acute-phase proteins involved in connective tissue repair and clotting, as well as antioxidants and antiproteases. They also may function to counteract the hypoglycemic response to insulin overproduction during infection or stress.

Other alterations include a prominent leukocytosis, thrombocytosis, and the “anemia of chronic disease.” Metabolic changes include altered lipid metabolism and negative nitrogen balance. Changes in the chemical and enzymatic profile include increased hepatic production of metallothionein,

iNOS, heme oxygenase, manganese superoxide dismutase, and GSH. Plasma levels of zinc and iron are noted to drop, whereas copper levels increase slightly. This persists for the duration of inflammation and is likely due to sequestration induced by IL-6, glucocorticoids, and catecholamines. Low levels of iron and zinc may confer protective antimicrobial effects because they are essential for microbial growth.³⁹

Mediators of the Acute-phase Response. Bacterial products such as LPS are probably the most potent activators of tissue macrophages, the initiators of the acute-phase response. LPS, through its interactions with LPS-binding protein, CD14, and Toll-like receptors, induces macrophage synthesis of ROS, including NO; lipid derivatives such as PGE₂, thromboxane A₂, and PAF; and acute-phase cytokines. The primary signals inducing synthesis of acute-phase cytokines in the absence of bacterial infection may be free radicals, prostaglandins, or modified proteins acting like foreign materials.³⁹

Acute-phase cytokines can be proinflammatory (IL-1, TNF- α , IFN- γ , IL-8) or anti-inflammatory (IL-10, IL-4, IL-13, TNF- β). However, it is IL-6- and IL-6-type cytokines that are most critical in the acute-phase response. IL-6 is the major inducer of acute-phase protein synthesis and, together with IL-1 and TNF- α , is responsible for the systemic features classically associated with the acute-phase response (fever, anorexia, leukocytosis, and hormonal changes).³⁹

In addition to the aforementioned cytokines, IFN- γ is a potent inducer of complement components. The anti-inflammatory cytokine TGF- β stimulates synthesis of antiproteases, urokinase, and negative acute-phase proteins. IL-4 is inhibitory to some acute-phase proteins. Growth factors, including hepatocyte growth factor and TGF- β , are also able to modulate the synthesis of acute-phase proteins. Glucocorticoids augment the response to cytokines, and insulin attenuates the cytokine-induced rise in acute-phase proteins.³⁹

Effects of the cytokines are influenced by cytokine receptors, receptor antagonists, and hormones. IL-1RA competes with IL-1 and attenuates the acute-phase response in vivo. Soluble receptors for IL-1 and TNF- α act as antagonists. In contrast, soluble receptors for IL-6 act as agonists.

Regulation of Acute-phase Cytokines and Proteins. Several major families of transcription factors participate in the upregulation of acute-phase cytokines and proteins, the most important being NF-IL-6, AP-1, and NF- κ B.²⁶⁰ NF-IL6 participates in the induced expression of the cytokines IL-1, TNF- α , IL-6, and IL-8, among others. Activation of cytokine gene expression by NF- κ B is probably the most important pathway. The triggering of IL-6 in monocytes in vitro by IFN- γ involves a change in the amount of the phosphorylated transcription factor Sp1, together with the induction and activation of IFN-regulatory factor.

All known acute-phase proteins are regulated primarily at the transcriptional level. Activation of TNF- α and IL-1 receptors triggers signaling pathways that activate transcription factors AP-1 and NF- κ B. Many type I acute-phase protein genes contain response elements for NF- κ B, NF-IL-6, and AP-1. Acute-phase protein responses to IL-6 are mediated through the JAK/STAT signal transduction pathway. In addition, both IL-1 and IL-6 signal transduction mechanisms activate the MAPK pathway that activates transcription factor NF-IL-6, linking the IL-1 and IL-6 pathways.

Reperfusion Injury

Prolonged tissue ischemia produces irreversible injury and cell death. Timely restoration of perfusion may salvage some tissue, though paradoxically can induce injury as well. Reperfusion injury is the damage caused by the restoration of blood flow in previously ischemic tissue (i.e., myocardial ischemia,

transplantation, vascular surgery). Injury is the direct consequence of activation of the inflammatory response, especially complement activation and neutrophil recruitment. Components of the complement cascade promote tissue damage through the generation of anaphylatoxins and by the formation of the MAC. Invading neutrophils injure tissue through the generation of ROS and the release of proteolytic enzymes. Recent evidence points to TLR4 as a sensor of tissue stress probably through the release of DAMPs from ischemic cells.³² TLR4 stimulation leads to the activation of local and systemic inflammation in both warm and cold reperfusion. This inflammation contributes to tissue damage in this setting.

Alterations in the microvascular endothelium are central to the pathophysiologic process of reperfusion injury. Early loss of constitutive NO production facilitates neutrophil adherence and the upregulation of cell adhesion molecules such as P-selectin, and inhibits vasorelaxation and perfusion.²⁶¹ Low oxygen tension induces the conversion of xanthine dehydrogenase to xanthine oxidase. Reperfusion and reoxygenation yield the formation of superoxide anion and H₂O₂ and induce oxidant injury. Neutrophils and other cellular effectors are progressively recruited and activated, releasing ROS, cytokines, and NO, further contributing to increased vascular permeability and tissue injury. PAF released by neutrophils activates circulating platelets and promotes vascular plugging. Platelets also release factors that enhance platelet-neutrophil adhesion. Both cell types also release vasoconstricting agents that can further exacerbate no-reflow. Capillary plugging by neutrophils and platelets can impair local blood flow and cause the “no-reflow phenomenon.”³⁹

Neutrophils mediate direct toxicity to the surrounding tissue through the elaboration of ROS and granule contents. Peroxynitrite formed by the reaction of NO and superoxide can contribute directly to tissue injury during reperfusion. Neutrophil granule proteases such as elastase, collagenase, and gelatinase alter the vascular permeability and are highly destructive to local tissue. The significance of the neutrophil in mediating these effects is apparent in neutrophil depletion studies demonstrating attenuated tissue injury compared with subjects with normal numbers of neutrophils.²⁶² Animal studies using blocking monoclonal antibodies to selectins and β_2 integrins show improved organ function ischemia/reperfusion.²⁶³

The mechanism by which complement is activated with reperfusion is not completely understood. Ischemia may alter the cell's plasma membrane or through the exposure of basement membrane or subcellular organelle components, creating a complement-activating surface. Alternatively, binding of natural antibody may lead to induction of these cascades.¹⁷¹ Complement activation has been shown to occur in the setting of therapeutic thrombolysis. The generation of plasmin-dependent fibrinolytic agents and plasmin after tissue plasminogen activator administration has been associated with complement activation.²⁶⁴

Anaphylatoxins are important effectors of complement-mediated injury. They alter vascular permeability and induce smooth muscle cell contraction and the release of histamine from mast cells and basophils. C3a and C5a are potent chemoattractants especially for neutrophils. C5 can be activated by oxygen free radicals, which are abundant. The subsequent generation of the MAC perturbs the maintenance of vital ion gradients, induces cell lysis, and facilitates neutrophil recruitment. In addition, it can induce the expression of numerous inflammatory mediators, including cytokines (TNF- α , IL-1, IL-8), ROS, prostaglandins, leukotrienes, and cell surface adhesion molecules.²⁶⁵

Systemic Inflammatory Response Syndrome

The inability of host defenses to control a localized inflammatory process or an unchecked inflammatory response can

results in SIRS. A recent consensus conference defined SIRS as the presence of any two of the following physiologic parameters: (a) a temperature greater than 38°C or less than 36°C; (b) leukocytosis ($>12,000$), leukopenia ($<4,000$), or more than 10% bands; (c) pulse greater than 90 beats per minute; and (d) tachypnea (respiratory rate >20 or $\text{PaCO}_2 <32$ mmHg).²⁶⁶ Infection underlies a significant minority of cases as a third of patients with SIRS will have a documented infection and meet the criteria for sepsis. There is a continuum from the development of SIRS to sepsis, severe sepsis, septic shock, and MODS.²⁶⁷ The outcome depends on the balance between SIRS and host compensatory mechanisms. In one prospective study, 26% of patients with SIRS developed sepsis and 7% died.²⁶⁸

SIRS may be initiated by infectious or noninfectious causes, such as trauma, autoimmune reactions, or pancreatitis. Gram-negative organisms, rich in LPS, induce a potent inflammatory response mediated through the CD14/TLR4/MyD88 pathway previously described and account for the majority of infectious SIRS cases. Gram-positive organisms can generate a similarly impressive degree of inflammation either through TLR2 or alternative mechanisms; streptococcal superantigen may induce a global and nonspecific activation of T cells that culminates in massive systemic elaboration of cytokines and cardiovascular collapse termed *toxic shock syndrome*. Trauma, either through tissue injury (HMGB1–RAGE, HSP–CD91) or the ischemia/reperfusion consequent to hemorrhage, can culminate in inflammatory pathophysiology indistinguishable from that accompanying these other inflammatory states. As evidence continues to grow, we are replacing the former concept that these stimuli possess individual receptor-signaling mechanisms with one that emphasizes the similarities and integration. Though there are clearly mechanisms by which the host distinguishes normal self from endogenous (trauma) and exogenous (infection) dangers, there is considerable overlap in the receptors utilized and all stimuli appear to converge upon signaling mechanisms in attaining the goal of preserving the host.

The development of SIRS has been described as progressing through three stages: stage I, local cytokine production recruits inflammatory cells to the injured site; stage II, an acute-phase response is initiated and small quantities of cytokines are released into the circulation to enhance the local response; and stage III, homeostasis cannot be reestablished.²⁶⁹ Enhanced levels of CRP, the major acute-phase protein in humans, occur in SIRS/sepsis, and clinical resolution is preceded by a drop in CRP levels.

The elaboration of proinflammatory cytokines (IL-1, TNF- α , and IL-6) is central to the pathogenesis of SIRS regardless of the initiating stimulus. Their elaboration triggers increased expression of adhesion molecules, leukocyte recruitment, and the production of secondary proinflammatory mediators, such as chemokines. Endotoxin, or LPS, is one of the most powerful triggers of SIRS. LPS activates the complement and coagulation cascades, induces endothelial cell activation, and increases TNF- α and IL-1 synthesis and the late release of HMGB1. However, noninfectious tissue injury induces a similar inflammatory response. LPS, TNF- α , and IL-1 also induce increased production of NO by iNOS in macrophages and other inflammatory cells. PGI₂, along with other metabolites or arachidonic acid, together with NO contributes to decreased systemic vascular resistance and hypotension. Autocrine and paracrine NO production also results in myocardial depression. Increased vascular permeability promotes extravasation of fluid and edema formation. Activated endothelial cells express tissue factor, PECAM, and TXA₂, which promote a procoagulant local environment that predisposes to microthrombi formation. Adherent leukocytes further exacerbate organ injury by mechanically impeding microvascular blood flow and by damaging the endothelial cells and surrounding connective tissue. The results are end-organ hypoperfusion, inadequate oxygen delivery, initiation of anaerobic

metabolism, and end-organ failure. The metabolic and nutritional sequelae of this activated cytokine milieu includes fever, catabolism, cachexia, and altered fat, glucose, and trace mineral metabolism.

SIRS is counteracted by the concomitant induction of an anti-inflammatory response termed the *compensatory anti-inflammatory response syndrome* (CARS).²⁶⁹ Many of the proinflammatory mediators that participate in SIRS modulate the immune function of lymphocytes and mononuclear cells. Proinflammatory mediators can inhibit their own synthesis or enhance the synthesis of natural antagonists by negative feedback mechanisms. Thus, at any given time, the clinical manifestation is SIRS, CARS, or an intermediate, mixed inflammatory response syndrome. The spectrum of features that characterize these syndromes has been termed *CHAOS* (cardiovascular shock, homeostasis, apoptosis, organ dysfunction, and immune suppression). Studies employing a variety of specific anticytokine agents have failed to observe an improvement in the outcome of patients with SIRS or sepsis. However, two studies of immunomodulation have noted significant effects in septic populations. The PROWESS study of activated protein C underscores the importance of the coagulation cascade during inflammation. This randomized controlled trial noted a 19.6% relative reduction and a 6.1% absolute reduction in mortality for those patients with severe sepsis who received activated protein C.²⁷⁰ Another study used a combination of corticosteroid and mineralocorticoid replacement for those patients with sepsis who had relative adrenal insufficiency as defined by a less than 10 unit increase in cortisol after a Cortrosyn stimulation test. They documented a 33% related reduction and 10% absolute reduction in the risk of death for those patients who received steroids.²⁷¹

Chronic Inflammation

There are no clear boundaries between an acute and a chronic inflammatory response. In general, if the source of an acute inflammatory process is incompletely eliminated, a state of chronic inflammation eventually ensues. Chronicity is usually not characterized by the signs classically associated with acute responses, such as swelling, heat, or redness. Pain is minimal if not absent. Microscopically, a mononuclear cell infiltrate predominates (lymphocytes, monocytes, plasma cells) with proliferation of fibroblasts and vascular elements.

Many agents can create a state of chronic inflammation, including persistent infectious agents, remnants of dead organisms, foreign bodies, and metabolic byproducts. Ultimately, chronicity of inflammation is a result of the immune response to a persistent antigen. Furthermore, a chronic inflammatory response can develop in the absence of a preceding acute response, such as infections with agents of low toxicity such as mycobacterium and treponema. CD4⁺ T cells and macrophages are the primary cellular orchestrators of the chronic inflammatory response.²⁷² T_H1 cell-mediated immunity (CMI) responses are protective against most microbes and usually result in the elimination of the pathogen. If the microbe persists, the ongoing T_H1 response results in inflammatory tissue injury. Cytokines and growth factors released by T lymphocytes and macrophages stimulate proliferative responses. Neutrophils and eosinophils contribute to the release of proteolytic enzymes and oxygen derivatives. Eosinophilia occurs with chronic parasitic infections and hypersensitivity conditions. Fibroblasts are actively recruited by chemoattractants such as fibrin, collagens, and cytokines. Local IL-1 stimulates fibroblast proliferation and collagen production. Irreversible tissue damage can occur through the replacement of normal parenchyma with fibrous connective tissue. Fibroblasts can release metalloproteinases that degrade normal tissue, further contributing to tissue destruction. Mast cells are elevated in chronic conditions and may play a part in cell-mediated

immune responses. Inflammatory cyst formation may occur as a result of epithelial hyperplasia.

CHAPTER 7 ■ SURGICAL INFECTIONS

E. PATCHEN DELLINGER

KEY POINTS

- 1 Surgical infections require surgical intervention, that is, “source control,” which refers to a mechanical or anatomic procedure to drain an abscess, relieve an obstruction, repair a perforation, or resect dead, ischemic, or inflamed tissue or foreign body to promote resolution.
- 2 Source control is combined with empiric antibiotic therapy that is later modified based on microbiologic susceptibility patterns.
- 3 Empiric antibiotic therapy requires knowledge of the current patterns of pathogens involved and antibiotic susceptibility within the institution and, even, specific units, such as the intensive care unit.
- 4 Surgical site infections are dependent on numerous factors, including extent of contamination, hemostasis, tissue handling, length of operation, tissue hypoxia, patient temperature, and glucose control, in addition to minimizing comorbidities.
- 5 Antibiotic prophylaxis should be dosed to maintain adequate tissue concentrations during the period of potential contamination, starting approximately 1 hour or less prior to surgery; repeated after one to two half-lives during prolonged operations, with increased doses in large patients; and stopped within 24 hours postoperatively if not immediately at the end of the operation. Choose a first-generation cephalosporin if no anaerobes are expected and add metronidazole if anaerobic activity is likely. Consider vancomycin only if there is a history of methicillin-resistant *Staphylococcus aureus* (MRSA) colonization or infection, for a dialysis patient or a patient with recent hospitalization or antibiotic treatment, or if there is a high rate of MRSA surgical site infections in your institution.
- 6 With peritonitis, antibiotics active against aerobic gram-negative organisms prevent early mortality and those active against anaerobic organisms prevent abscesses. Thus, broad-spectrum antibiotics are needed.
- 7 Necrotizing soft tissue infections are hard to diagnose, present with external skin changes underrepresenting the extent of underlying disease, and have potential for major tissue loss and high morbidity and mortality.

- 1 Although there is no official definition of a surgical infection, it is commonly understood as an infection that will not resolve with antimicrobial therapy alone but also requires surgical intervention, sometimes called source control. The intervention may be as significant as a major laparotomy or thoracotomy or as simple as removing sutures from an infected surgical incision or draining a superficial abscess. It also includes interventions by radiologists or other specialists such as computed tomography (CT)-guided percutaneous drainage of an intra-abdominal abscess or placement of a stent through a biliary stricture in a patient with cholangitis. A unifying characteristic of all surgical infections is an anatomic manipulation, such as draining a closed space, closing a perforated viscus, or removing dead tissue or foreign body, that must be performed to achieve resolution of the infection. Many “medical” infections involve single pathogens that are able to establish themselves and grow through intrinsic pathogenic mechanisms despite intact skin or mucosa. Examples include pneumococcal pneumonia, streptococcal pharyngitis, meningococcal meningitis, and salmonella enteritis. Surgical infections typically occur after a mechanical breach of normal epithelial barriers and often involve multiple organisms, typically endogenous to the area of epithelial injury. Examples include peritonitis after perforated appendicitis or diverticulitis and surgical site infections (SSIs) caused by skin flora after clean operations. An exception to this principle for surgical infections is the occurrence of necrotizing soft tissue infections secondary to group A β -hemolytic streptococci (hemolytic streptococcal gangrene) or community-associated methicillin resistant *Staphylococcus aureus* (CA-MRSA), which can occur following trivial injuries or no known prior injury. In this chapter we also discuss nonsurgical infections that typically occur in hospitalized surgical patients. These include catheter-related bloodstream infections, pneumonia, and urinary tract infections (UTIs).

In approaching the topic of surgical infections, each area is approached in the following order: prevention, diagnosis, treatment. The first element of prevention is the natural host defense mechanisms of the patient. The most important of these for surgical infections is the epithelial covering that separates the sterile portions of the body from those with normal endogenous flora. Thus, the skin on the outside of the body and the gastrointestinal (GI) mucosa lining the alimentary tract are the sites of complex microbiologic flora and serve to bar those flora from the tissues in most cases. Once these mechanical barriers are breached, by trauma, medical or surgical procedures, neoplasm, inflammation, or ischemia, cellular and humoral defenses become important.

The array of host defenses is large and complex, and our understanding of these processes is continually advancing. Initial, nonspecific defenses begin with fixed tissue macrophages and circulating polymorphonuclear leukocytes (PNMs), which engulf and kill small numbers of invading microorganisms. The macrophages and dendritic cells also have the ability to ingest pathogens and to process their antigens for presentation to T lymphocytes for the subsequent development of specific antibodies by B lymphocytes. The first presentation of an antigen leads to the formation of IgM class antibodies that are produced over the next 1 to 2 weeks. Subsequent exposure to the same antigen leads to much more rapid production of IgG antibodies. Antibodies bound to microorganisms promote more efficient phagocytosis and killing and also serve to activate complement proteins, another element in the humoral defense system. The complement system exists in a quiescent form, which when activated leads to a cascade of activated complement proteins and fractions that enhance phagocytosis, increase vascular permeability, stimulate inflammation, and lead to direct lysis of some pathogens.

There are many interactions between the cellular and humoral aspects of host defense. Host defense cells manufacture

the humoral components, and when activated, the humoral components stimulate the cells. In addition, there is extensive cross-talk among the cellular elements of host defenses involving a large number of cytokines including tumor necrosis factor (TNF) and many interleukins (ILs), signified by IL-*n*, with the number *n* increasing as new cytokines are discovered and characterized. The successful interaction of these elements is essential to normal host defenses, but when the mechanisms of control fail and cytokines spread beyond their intended local actions, these host defense mechanisms can turn against the host, resulting in a spectrum of conditions variously called the systemic inflammatory response syndrome (SIRS) and multiple organ dysfunction syndrome (MODS). Many attempts to modify this process through the development of specific antagonists to various elements of this system have so far failed to produce clinically useful products, although research continues.

When injury occurs and blood vessels are opened, the coagulation cascade, similar in some ways to the complement cascade, is also initiated. In recent years it has been recognized that a number of elements in the coagulation response and the inflammatory response are shared, and local thrombosis and fibrinogen deposition are prominent components of acute inflammation. Inflammation stimulates a procoagulant state and can also promote distant thromboembolic events. More recently, a clinical trial of activated protein C, a component of the coagulation cascade that has antithrombotic, anti-inflammatory, and profibrinolytic properties, has proved beneficial for some patients with combined SIRS, infection, and organ failure.¹

PREVENTION

Despite the success of intrinsic host defenses, in many circumstances infections do occur, especially after surgical interventions, both elective and urgent. It is incumbent on the surgical team to understand and to apply what is known regarding elements of patient care and delivery of surgical procedures that reduce the risk of subsequent infection as much as possible. In general terms, these preventive measures can fall into three broad categories. The patient should come to an operative procedure with host defenses in the best possible condition. The procedure should be conducted in a manner that reduces to the minimum introduction of pathogens into the sterile compartments of the body. The perioperative management of the patient should be conducted in a manner that optimally supports and maintains the patient's host defenses. In actual practice, many items of patient care will relate to more than one of these goals. These items are discussed in more detail in the section dealing with SSIs.

DIAGNOSIS

Although details specific to the diagnosis of specific surgical infections and other infections in surgical patients are covered in those individual sections, some items of diagnosis are common to all. Some relatively straightforward infections such as superficial SSIs or subcutaneous abscesses are properly treated by simply opening the wound or draining the abscess without the use of antimicrobial agents and do not require routine culture. However, most surgical infections require at least the initial use of antimicrobial agents that are most effective if active against the primary pathogens involved. If initial treatment is clearly successful, then knowledge of the specific pathogens and their susceptibilities is not critical for the treatment of that patient. However, when the patient does not respond as expected, then knowledge of the pathogens and their susceptibilities can be extremely useful, and this information will not be available unless the appropriate cultures were obtained prior to initiating antibiotic therapy.

Material sent to the microbiology laboratory from the operating room or the interventional radiology suite is preferable. Surface swabs taken from open or draining wounds or material from drains that have been in place for days have a high probability of returning information about contaminating or colonizing organisms that are not responsible for the infection needing treatment. Samples of tissue or fluid are always preferable to swabs from the operating room. Blood cultures are helpful when positive but are positive in less than one third of surgical infections in most reported series. An early source of information from such specimens is the Gram stain, which should be available to the physician in less than an hour after obtaining the specimen. The initial choice of antimicrobial agents for a serious infection will be quite different if the Gram stain shows gram-positive cocci than if the stain shows predominantly gram-negative rods. Microbial growth and preliminary identification will usually be available within 24 hours for most surgical pathogens, but susceptibility information will not be reported for 1 or more additional days. Thus, knowledge of the susceptibility patterns in the hospital, or even more specifically, in a specific intensive care unit (ICU), can be invaluable in directing initial empiric antimicrobial choices for a critically ill patient.² This is another reason to culture severe infections. The body of information about pathogens and their susceptibilities locally helps to direct therapy for patients in the future, and these patterns can change over time. Thus, current culture information is always helpful. Although antimicrobial susceptibility data currently take 2 days or more in most cases, advances in the modern microbiology laboratory may someday provide this information more rapidly. Detection of specific nucleic acid sequences has the potential to identify certain common and well-characterized resistance genes such as the *mecA* gene that codes for methicillin resistance in *Staphylococcus aureus*. Other diagnostic advances that are making their way to the clinical microbiology laboratory include antigen and antibody detection systems and polymerase chain reaction (PCR) for amplifying small amounts of nucleic acids.

Diagnosis of infection always involves history and physical examination, but these are more efficiently discussed in relation to specific infections. Fever and leukocytosis are frequent accompaniments of infection but are not specific and are variously sensitive depending on the specific infection. They may drive further diagnostic efforts including physical and radiologic examination but are not sufficient reason to initiate antimicrobial treatment in isolation from other data. Radiologic examinations can be very helpful in some specific circumstances but should not substitute for or precede history and physical examination and clinical judgment.

TREATMENT

Treatment of surgical infections, as discussed initially in the definition of surgical infections, always involves a procedure and often involves the use of one or more antimicrobial agents. The generic term for a procedure directed at the resolution of a surgical infection is *source control*. Source control refers to the mechanical or anatomic procedure that is used to drain an abscess, relieve an obstruction, repair a perforation, or resect dead, ischemic, or inflamed tissue or a foreign body to promote the resolution of a surgical infection. In recent years there has been growing recognition that the literature regarding surgical infections is incomplete when it does not adequately describe and evaluate the effectiveness of source control.³ This is particularly true for publications comparing different antimicrobial treatments of surgical infections. When the differences between two regimens are small, a difference in the delivery of source control to patients in the comparative regimens can skew the results.⁴ The appropriate use of antimicrobial agents is also important in many situations and is addressed in the sections regarding specific infections.

Although the choice of specific agents, and to a lesser extent dosing, have been addressed, there are very little relevant data regarding the appropriate duration of antimicrobial treatment for most surgical infections. Trends in recent years have been to decrease this duration in many cases. Only in the area of prophylaxis are good data available.

SURGICAL SITE INFECTIONS

Infections that occur in a surgical incision were previously called wound infections. In recent years, a consensus conference involving surgical and medical societies and the Centers for Disease Control and Prevention (CDC) developed the concept of SSI.^{5,6} This includes any infection that occurs in an operative site. An infection of the subcutaneous tissue only (the most common “wound infection”) is termed a superficial SSI. One that involves the muscular and fascial layers and includes a partial or complete fascial dehiscence is a deep SSI. An infection that occurs within the organ or deep space of the wound such as peritonitis, an intra-abdominal abscess, an empyema, or a joint space infection is called an organ/space SSI. Data from the National Nosocomial Infection Surveillance (NNIS) system of the CDC shows that of all SSIs, 47% are superficial, 23% are deep, and 30% are organ/space.⁷ Only 46% of these SSIs are diagnosed during the original hospitalization, whereas 16% are diagnosed after discharge as outpatients and 38% on readmission to the hospital. Although 58% of all organ/space SSIs are diagnosed during the original hospitalization, 59% of other SSIs are diagnosed only after discharge.⁷

Surgeons have traditionally divided wounds into the classes of clean, clean-contaminated, contaminated, and dirty (Table 7.1)⁸ based on the probability that the wound would be contaminated by bacteria during the operative procedure. These classes roughly divide wounds into different risks for the development of SSI. More recently, examination of databases that include many thousands of wounds have led to the development of newer risk classification systems that provide a more accurate estimate of risk. The NNIS index⁹ assigns up to

TABLE 7.1 CLASSIFICATION

WOUND CLASSIFICATION

■ CLASS	■ DEFINITION
Clean	An uninfected operative wound in which no inflammation is encountered and the respiratory, alimentary, genital, or infected urinary tract is not entered. In addition, clean wounds are closed primarily
Clean-contaminated	An operative wound in which the respiratory, alimentary, genital, or urinary tracts are entered under controlled conditions and without unusual contamination
Contaminated	Open, fresh, accidental wounds. Operations with major breaks in sterile technique or gross spillage from the gastrointestinal tract, and incisions in which acute, nonpurulent inflammation is encountered
Dirty	Old traumatic wounds with retained devitalized tissue and those that involve existing clinical infection or perforated viscera

TABLE 7.2 CLASSIFICATION

COMPARISON OF WOUND CLASSIFICATION AND NNIS SYSTEM FOR EVALUATING RISK OF SURGICAL SITE INFECTION

■ WOUND CLASS	■ NNIS RISK INDEX				
	■ 0	■ 1	■ 2	■ 3	■ ALL
Clean	1.0	2.3	5.4	—	2.1
Clean-contaminated	2.1	4.0	9.5	—	3.3
Contaminated	—	3.4	6.8	13.2	6.4
Dirty	—	3.1	8.1	12.8	7.1
All	1.5	2.9	6.8	13.0	2.8

one risk point for each of (a) contaminated or dirty wound, (b) American Society of Anesthesiologists (ASA) class 3 or higher, and (c) duration of operation exceeding the 75th percentile for that operation.⁹ Thus, an operation may fall into one of four classes between 0 and 3. Table 7.2⁹ demonstrates the increased precision of this system compared with the older system that refers only to wound class. This system can be used to roughly compare the performance of a hospital or surgical department against the NNIS database by comparing expected with observed infection rates.¹⁰ Of course, much more precise risk data can be developed for single operative procedures through analysis of large databases in which the heterogeneity imposed by multiple different procedures is eliminated.^{11,12}

Many other factors that influence the risk of SSI have been proposed, and a relatively complete summary of these factors is provided in a publication by the Hospital Infection Control Practices Advisory Committee (HICPAC) of the CDC.⁶ Some of these are summarized in Table 7.3, which lists the category 1 recommendations that are readily influenced by the surgeon. It is likely that the majority of these are important in most operative procedures, although most have been generated through analysis of single procedures or limited classes of procedures and have not been reproduced in all cases. Many, such as the patient's weight and smoking status or the presence of an infection at a distant site, are modifiable prior to scheduled operation. Others, such as age or underlying immune disorders, cannot be improved. Some, such as diabetes, cannot be eliminated, but recent information suggests that tight control of perioperative glucose levels can greatly reduce the risk associated with this diagnosis.^{13–15}

Prevention

- Preventing SSIs is clearly a prime responsibility of any operating surgeon. Although many surgeons think first of prophylactic antibiotics for prevention, and these are clearly important, antibiotics are most effective when they complement maximal efforts for prevention by other means. Two classic papers on surgical prophylaxis, each of which demonstrated the superiority of prophylactic antibiotics to placebo in randomized prospective trials, also demonstrated an increased infection

TABLE 7.3 TREATMENT**CATEGORY 1 RECOMMENDATIONS FROM THE HOSPITAL INFECTION CONTROL PRACTICES ADVISORY COMMITTEE FOR THE PREVENTION OF SURGICAL SITE INFECTIONS**

- Do not operate on patients with active infections.
- Do not shave patient in advance.
- Control glucose in diabetic patients.
- Stop tobacco use in patient.
- Have patient shower with antiseptic soap.
- Prepare skin with appropriate agent.
- Surgeon's nails should be short.
- Surgeons scrub hands.
- Exclude infected surgeons.
- Give prophylactic antibiotics when indicated.
- Maintain prophylactic antibiotic levels during operation.
- Keep operating room doors closed.
- Use sterile instruments.
- Avoid flash sterilization.
- Wear a mask.^a
- Cover all hair.^a
- Wear sterile gloves.^a
- Use gowns and drapes that resist fluid penetration.
- Handle tissue gently.
- Use closed suction drains (when used).
- Delay primary closure for heavily contaminated wounds.
- Use sterile dressing for 24–48 h.
- Use CDC definitions for SSI.
- Watch for SSI and give feedback to surgeons.

CDC, Centers for Disease Control and Prevention; SSI, surgical site infection.

^aThese items are required by Occupational Safety and Health Administration (OSHA) regulations and are not actually supported by class 1 data.

From Mangram AJ, Horan TC, Pearson ML, et al. Guideline for prevention of surgical site infection, 1999. Hospital Infection Control Practices Advisory Committee. *Infect Control Hosp Epidemiol*. 1999;20:250–278, with permission.

rate in the face of prophylaxis when hemostasis was not ideal¹⁶ or when gross contamination was observed during the operative procedure.¹⁷ Each patient should be brought to the operating room only after the correctable items noted in Table 7.3 have been corrected to the degree possible. In addition, in recent years several elements of the immediate perioperative management of surgical patients have been demonstrated to have a significant effect on the risk for SSI. Beyond these issues, most surgeons believe that the technical conduct of the operation, including the handling of tissues, number of ties and other foreign material and devitalized tissue, and length of operation, all influence the risk of SSI. Unfortunately, no validated method for assessing these issues exists. In addition, although data clearly demonstrate that the risk for SSI increases with increasing duration of operation and increasing transfusion, it is not clear that operations that take longer or require more transfusion are the same as shorter procedures that do not require transfusion. Thus, the precise role of these issues is not clear. Certainly, no surgeon should take longer than he or she thinks necessary for a procedure, nor should he or she transfuse a patient when it is not considered important.

Inspired Oxygen Tension. Multiple animal models of infection demonstrate that oxygen tension within the surgical wound correlates with risk for SSI. Low oxygen tensions increase risk, whereas higher tensions decrease it.¹⁸ Another report examined the subcutaneous oxygen tension in 130 surgical patients in the postanesthesia recovery room.¹⁹ The same inverse relationship was found between oxygen tension and

risk for SSI. Recently, a prospective trial comparing inspired oxygen concentrations of 30% to 80% in patients having a colectomy demonstrated a significant decrease in infection rates in the high-inspired-oxygen group.²⁰ Subsequently, two papers from different groups of investigators have reported both contradictory and confirmatory results. One was a much smaller study of patients having mixed GI procedures and poorly balanced comparative groups with an opposite conclusion, a higher infection rate in the patients receiving 80% oxygen compared with 35%.²¹ The other was a larger, well-done multicenter study that showed a clear reduction in SSI risk with 80% fraction of inspired oxygen (FiO₂) compared with 30%, but both groups had relatively higher infection rates than the first two studies.²² Until more data are available, we must consider the ideal inspired oxygen concentration for reducing risk of SSI in surgical patients to be unsettled, although the preponderance of evidence leans toward a benefit to higher levels of FiO₂.²³

Temperature Control. The temperature of a patient in the operating room is known to influence skin and subcutaneous blood flow and oxygen tension.²⁴ Animal models have demonstrated increased infection risk when body temperature is lowered. Recently, two prospective controlled trials have demonstrated a reduction in SSI in patients who were actively warmed. One trial in patients submitted to colectomy compared active warming in the operating room to no efforts at warming.²⁵ A threefold reduction in infection rate was found in the warmed patients. In another study of minor procedures (hernia repair, varicose vein operation, or breast procedure with incision >3 cm), active prewarming, either of the whole patient or of the operative site, also significantly reduced the incidence of SSI and of postoperative antibiotic use by physicians blind to the treatment group.²⁶ It is increasingly the standard to maintain normal body temperature for operative patients, but without specific protocols to achieve this in all patients, it frequently is not achieved.²⁷

Glucose Control. It has long been known that diabetics have a higher risk for SSI than nondiabetic patients. It has been assumed that this is related to underlying defects in host defense associated with the diagnosis. Recently, analysis of a large series of patients, both diabetic and nondiabetic, having an open heart procedure demonstrated that the risk for SSI was most strongly correlated with the occurrence of hyperglycemia (glucose >200 mg/dL) during the first 48 hours after operation.¹³ When this occurred, the risk for SSI was doubled regardless of whether the patient was diabetic or not. Forty-seven percent of the patients with hyperglycemia in this study were not diabetic. This relation has also been shown for a group of mixed GI and cardiovascular operations in diabetic patients.²⁸ Another cardiac surgery group has shown the same relationship between glucose levels and infection risk and has also demonstrated that improved perioperative glucose control with intravenous insulin infusions has reduced both the incidence of SSI and mortality in their diabetic patients.^{14,29} Although the strongest evidence exists for diabetic cardiac surgical patients, it is likely that all hyperglycemic surgical patients will benefit from perioperative glucose control.¹⁵

Antibiotic Prophylaxis. Antibiotic prophylaxis for surgical procedures began shortly after the initial introduction of penicillin with the hope that antibiotics would reduce the risk of surgical wound infections. Prior to 1960, prophylactic antibiotics commonly were started after surgery, a technique that we now know is ineffective. Furthermore, antibiotics were given most often to patients at special risk of infection. Consequently, patients given antibiotics were more likely to develop infections than untreated patients.³⁰ Subsequent animal experiments and human trials demonstrated that giving antibiotics before wound contamination occurred (i.e., preoperatively)

TABLE 7.4

RESULTS

TYPICAL INFECTION RATES AND REDUCTION WITH PROPHYLAXIS

	■ PROPHYLAXIS (%)	■ PLACEBO (%)	■ NNT ^a

GI, gastrointestinal.

^aApproximate number needed to treat (NNT) to avoid one surgical site infection.

significantly reduced SSI.³¹ Subsequent study has shown that the ideal time for antibiotic administration is just before the incision because this regimen produces better tissue antibiotic concentrations at both the beginning and end of the operation than other administration times.^{32–35}

Prophylactic antibiotics are indicated for all GI (including appendectomy), obstetric, gynecologic, oropharyngeal, vascular (abdominal and leg), and open heart procedures. Typical reductions in SSI rate in early placebo-controlled trials of prophylactic antibiotics are given in Table 7.4. The use of prophylactic antibiotics for clean operations remains controversial. Although prophylactic antibiotics reduce the infection rate even in clean procedures, the baseline infection rate is low in these cases.^{36,37} Consequently, the number needed to treat for each infection prevented is so large that the reduction in infection risk may not justify the cost and complications associated with antibiotic administration. Nonetheless, prophylactic antibiotic treatment is used routinely for clean procedures such as open heart operations, joint replacement, vascular prostheses, and craniotomy, in which the consequences of SSI are especially severe.³⁸

- 5 Antibiotics should be dosed to maintain adequate tissue concentrations throughout the period of potential contamination. For example, doses should be increased in larger patients.³⁹ Similarly, doses should be repeated after one or two half-lives have elapsed.^{40,41} Numerous trials comparing shorter and longer durations of prophylactic antibiotics failed to show any benefit of extending antibiotic administration beyond the operating room.^{42,43} Furthermore, prolonged prophylaxis is associated with recovery of resistant bacteria.⁴⁴ An expert panel assembled by the Center for Medicare and Medicaid Services (CMS) thus recommended that prophylactic antibiotics be initiated within the hour before starting an operation and stopped within 24 hours of completion.⁴⁵

Naturally, the antibiotic(s) must be active against the relevant pathogens. This is most clearly illustrated by the requirement that the agent used have activity against enteric anaerobes for procedures involving the lower GI tract. Although yet to be studied in a systematic manner, there is general agreement that antibiotic agents used for prophylaxis should be different from agents usually chosen as first-line treatment of established infections. Thus, although imipenem/cilastatin or piperacillin/tazobactam would undoubtedly be efficacious as prophylactic agents for colon operations, they are not recommended for this purpose. Table 7.5 gives the spectrum of antibiotic recommendations that have been published by different professional societies and organizations. In general, one can choose a first-generation cephalosporin for operations not

expected to encounter anaerobes and a second-generation cephalosporin with anaerobic activity for procedures in which anaerobic contamination is likely.

β -Lactam allergies are often cited as a problem for surgical antibiotic prophylaxis. However, many patients reported as allergic do not have true allergy and instead have experienced minor adverse reactions such as *Candida* overgrowth or GI upset. Before choosing an alternate prophylactic agent, one should confirm the nature of the previous reaction. Patients who have had immediate, anaphylactic-type reactions should not receive a cephalosporin, but most others can safely receive one or two doses in the perioperative period. For patients with true β -lactam allergies, vancomycin is the most common prophylactic choice when the primary risk of infection is from skin organisms, and clindamycin is another appropriate alternative. There are no controlled trials of prophylaxis in colon operations using agents appropriate for β -lactam-allergic patients. Logic suggests that the combination of clindamycin or metronidazole with either an aminoglycoside or a fluoroquinolone or the combination of clindamycin with aztreonam should be effective. Although vancomycin has been recommended for routine prophylactic use in hospitals with high rates of methicillin-resistant *Staphylococcus aureus* (MRSA), infection rates were not reduced in the only relevant prospective trial, and the number of infections due to sensitive staphylococci was increased in the vancomycin arm.⁴⁶ Vancomycin prophylaxis appears to be most appropriate in patients proved by preoperative nasal culture to be MRSA carriers.

Shaving. Removing hair at the operative site remains routine in many settings, although there is no evidence that it reduces infection rate. In contrast, studies show that avoiding hair removal or using depilatories rather than shaving reduces infection rates after clean operations.^{47,48} For example, infection rates are reduced when hair is clipped rather than shaved, even when performed on the day of operation. It may be helpful to warn patients not to shave their operative sites before surgery as some do in an effort to be helpful. If hair removal at the incision site is considered necessary, it should be performed with clippers during the immediate preoperative period.

Delayed Primary Closure. A classic technique to avoid SSI has been to leave the wound open at the original procedure and then to attempt delayed primary closure a few days later or to leave the wound open for closure by secondary intention. This practice was widely used by the military during World War II, and although there have been many series recommending this practice, it has rarely been subject to controlled trial.

TABLE 7.5

MANAGEMENT

SUMMARY OF PUBLISHED GUIDELINES ON ANTIMICROBIAL PROPHYLAXIS FOR OPERATIONS TARGETED FOR SURVEILLANCE IN THE NATIONAL SURGICAL CARE IMPROVEMENT PROJECT (SCIP)

■ OPERATIONS	■ PROPHYLACTIC ANTIBIOTIC RECOMMENDATION	■ COMMENTS
Cardiothoracic surgery	Cefazolin Cefuroxime Vancomycin If β -lactam allergy: Vancomycin Clindamycin	Stop within 48 h of end of operation. The Society of Thoracic Surgeons (STS) Practice Guideline for Antibiotic Prophylaxis in Cardiac Surgery (2006) indicates that there is no reason to extend antibiotics beyond 48 h for cardiac surgery and very explicitly states that antibiotics should not be extended beyond 48 h even with tubes and drains in place for cardiac surgery.
Vascular surgery or hip or knee arthroplasty	Cefazolin Cefuroxime Vancomycin If β -lactam allergy: Vancomycin Clindamycin	Stop within 24 h of end of operation. Although not addressed in any of the published guidelines, the workgroup recommends that the prophylactic antimicrobial be completely infused prior to the inflation of a tourniquet.
Colon surgery	Parenteral: Cefoxitin or cefotetan or ampicillin-sulbactam or ertapenem OR Cefazolin plus metronidazole or cefuroxime plus metronidazole If β -lactam allergy: Clindamycin plus an aminoglycoside or a quinolone or aztreonam OR Metronidazole plus an aminoglycoside or a quinolone	Prophylaxis should stop within 24 h of end operation.
Vaginal or abdominal hysterectomy	Cefazolin Cefotetan Cefoxitin Cefuroxime Ampicillin-sulbactam If β -lactam allergy: Clindamycin plus an aminoglycoside or a quinolone or aztreonam OR Metronidazole plus an aminoglycoside or a quinolone OR Clindamycin monotherapy OR Metronidazole monotherapy	Prophylaxis should stop within 24 h of end operation.

A recent prospective trial randomized patients undergoing an operative procedure with dirty wounds either to have primary closure of the incision or to have it left open with delayed primary closure.⁴⁹ Although the authors concluded that there were fewer SSIs in the group with wounds left open, it is instructive

that there were very few differences in overall patient course, and more patients went home with open wounds requiring dressing changes when the wounds were left open than when they were closed primarily in the operating room. There were no differences in overall hospital stay or in charges.

Diagnosis of Surgical Site Infection

One can easily diagnose an SSI when the wound opens and discharges pus. However, it is preferable to make the diagnosis earlier and to initiate prompt intervention. Most SSIs are not clinically evident before the fourth or fifth postoperative day. The rare exceptions to this are infections caused by β -hemolytic streptococci and by histotoxic *Clostridium* sp. and, even more rarely, wound toxic shock. These can be evident within 1 day and, although rare, can be very severe. If a patient manifests severe systemic signs of infection during the first few days after an operation, the incision should be inspected for signs of infection (Algorithm 7.1). Streptococcal infections usually have local signs of inflammation with marked erythema and pain and wound fluid containing white blood cells (WBCs) and gram-positive cocci. Wounds infected by clostridia usually lack signs of inflammation but cause severe pain out of proportion to other findings and drain a thin, brackish wound fluid lacking leukocytes due to the action of the exotoxins on leukocytes inhibiting migration and causing lysis. In these cases, gram-positive rods without spores are evident on Gram smear. Wound blisters or desquamation of skin associated with SSI are late findings and predictive of significant morbidity.

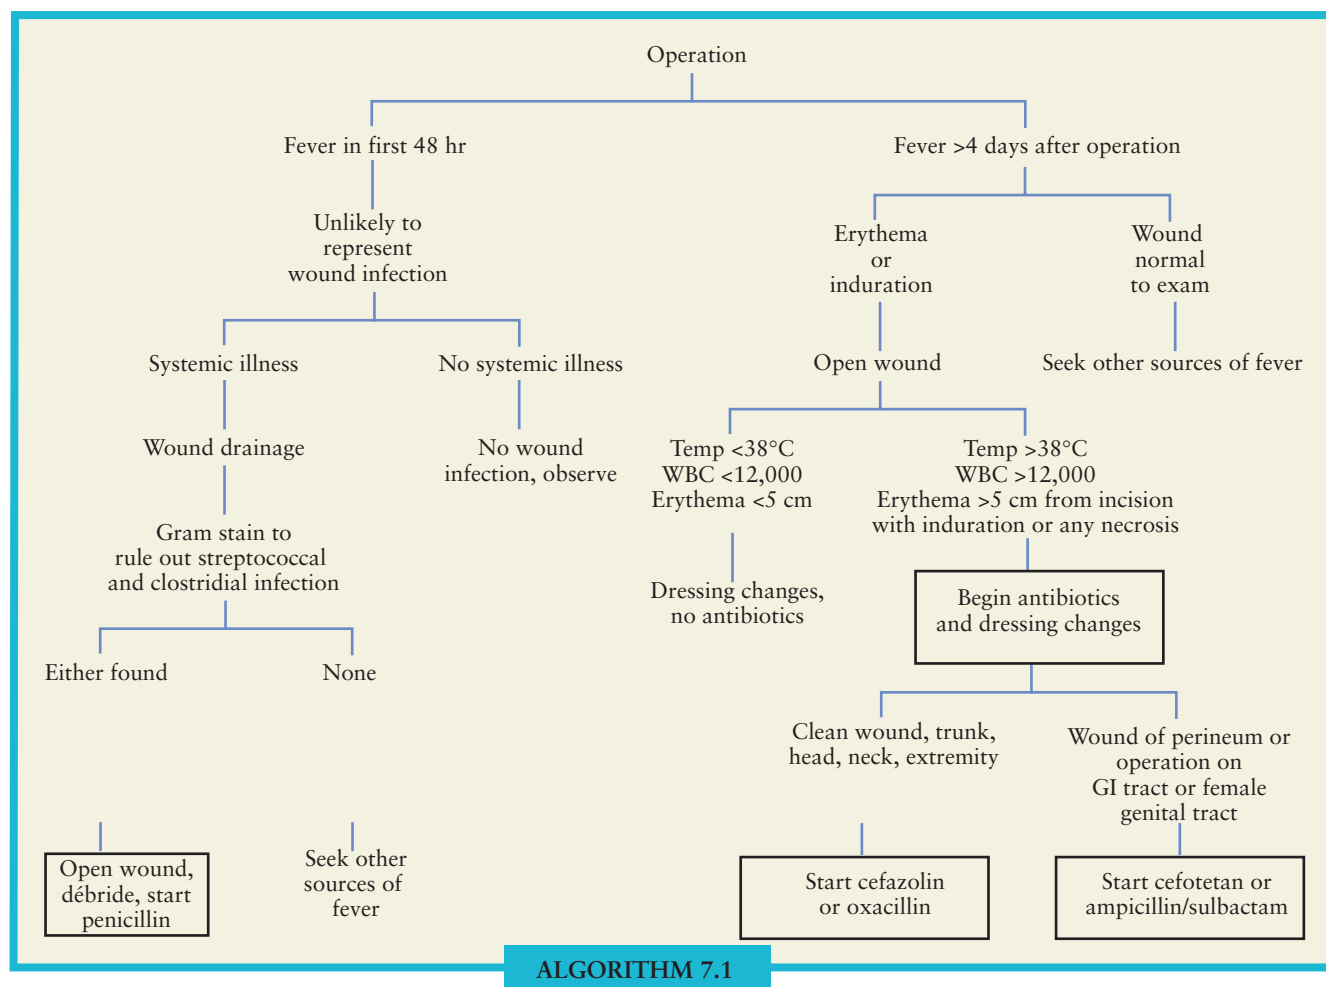

Thirteen cases of wound toxic shock were confirmed by the CDC during an 18-month period, representing less than 1% of all cases of toxic shock reported during that period. More than half of these presented within 48 hours of an operation.⁵⁰ The

earliest signs were fever, diarrhea, and vomiting. Erythroderma and hypotension were also present. Often, local signs of wound infection were initially absent. Drainage and irrigation of the wound in combination with a systemic antistaphylococcal antibiotic is recommended.

Although most wound infections are diagnosed within 2 weeks after the procedure, diagnosis may occasionally be considerably delayed. This is more likely when a significant amount of tissue covers the operative site such as abdominal incisions in morbidly obese patients. Because many patients have some fever in the first several days after a major operative procedure even without infection, fever is not a specific sign of postoperative infection (Fig. 7.1).⁵¹ Many surgeons want to continue prophylactic antibiotics or to restart antibiotics in cases with early postoperative fever, but this is unlikely to be helpful. In addition, SSI cannot be treated without opening the incision. If antibiotics are given for an SSI without opening the wound, this can result in a delay in diagnosis and definitive treatment, additional morbidity, and additional complications such as wound dehiscence.

Therapy

The most important treatment for an SSI is to open the incision and evacuate the infected material. Antimicrobial agents are needed only when a patient exhibits a significant systemic response to the infection or when there is clinical evidence for

ALGORITHM 7.1. Managing potential surgical site infections. (Adapted from Dellinger EP. Post-operative wound infections. In: Schlossberg D, ed. *Clinical Infectious Disease*. New York: Cambridge University Press; 2008:769–773.)

FIGURE 7.1. Percentage of all postoperative fevers occurring on the indicated day following an operative procedure. Lines indicate the percent of fevers occurring on each day attributable to the cause indicated. (After Dellinger EP. Approach to the patient with postoperative fever. In: Gorbach S, Bartlett J, Blacklow N, eds. *Infectious Diseases*. Philadelphia, PA: Lippincott Williams & Wilkins; 2004:817–823.)

invasive infection beyond the surgical wound. In most cases, the entire incision will be involved under the skin and will have to be opened. When an incision is first opened, it should be inspected by a surgeon who understands the procedure and the underlying anatomy. If the procedure was a laparotomy or a thoracotomy, the integrity of the closure of the abdominal or chest wall should be confirmed. In some cases, the incisional SSI is not the primary event but is a sign of more severe and more extensive infection at a deeper level, an organ/space SSI.

Antimicrobial agents should be started empirically at the time of diagnosis and opening of the wound only if there is a significant systemic reaction with temperature above 38°C, an elevated pulse rate, or an absolute WBC count above 12,000/mm³ or if there is invasive infection in the subcutaneous space or at the fascial level. The agent chosen should be determined by Gram stain of the wound contents and by the prior procedure. SSIs after an operation that did not enter the alimentary tract and was not on the perineum or axilla are often caused by *S. aureus* or less commonly streptococcal species. If Gram stain confirms gram-positive cocci, one can use an initial dose of cefazolin or oxacillin. Antimicrobial treatment should be continued only as long as systemic signs of infection or local cellulitis continues to be present, usually 3 days or less.

For SSIs that follow operations in the axilla, gram-negative bacilli are found more often, and after operations on the perineum or involving the alimentary or genital tract, both facultative and obligate anaerobes are common. In these cases, if antimicrobial therapy is necessary, treatment can be started with cefazolin plus metronidazole or perhaps ertapenem. Patients allergic to penicillin and cephalosporins can receive ciprofloxacin or levofloxacin combined with metronidazole. Again, the treatment should usually be 3 days or less.

INTRA-ABDOMINAL INFECTIONS

Prevention

Most intra-abdominal infections are the result of spontaneous disease including such conditions as appendicitis, diverticulitis, obstructed or perforated carcinomas, or inflammatory bowel disease. Here, prevention depends on early diagnosis and treatment of the underlying condition. However, an increasing proportion of intra-abdominal infections from series published in the past few decades have been postoperative, reflecting the increasing number of operative procedures performed, the increasing risk status of the patients, and the complexity of the operations performed. In the case of postop-

erative intra-abdominal infections, there are few data available regarding prevention. It is safe to assume that factors that reduce risk of incisional SSI after abdominal operations are probably helpful in the case of organ/space or intra-abdominal infections as well. In addition, avoidance of unintended injury to bowel and optimal performance of GI anastomoses are critical. When contamination of the peritoneum does occur, either during operation or because of spontaneous disease, natural host defense mechanisms actually deal very successfully with small inocula by a combination of lymphatic clearance and phagocytosis by local macrophages. However, if contamination with a small inoculum is repeated, abscess formation is likely. And, if continued contamination occurs, local defenses are overwhelmed and peritonitis results.

Diagnosis

Intra-abdominal infections are usually divided into peritonitis, a poorly localized infection of the peritoneal space, or intra-abdominal abscess, a localized infection within the abdomen. Peritonitis can be relatively local within one quadrant or region of the abdomen, as in early gangrenous or perforated appendicitis, or diffuse in two or more abdominal quadrants. Diffuse peritonitis has a worse prognosis than peritonitis localized to one quadrant.⁵² Abscesses may occur within the free peritoneal space in the subphrenic regions, lateral gutters, pelvis, or interloop within the intestinal folds, or they may occur in the retroperitoneum or within a solid organ (visceral) such as liver or spleen. Peritonitis has traditionally been divided into primary and secondary peritonitis, and in recent years the concept of tertiary peritonitis has been proposed. Primary peritonitis describes those patients with ascites due either to hepatic cirrhosis or to nephrotic syndrome who develop infected ascites presumably secondary to bacteremia and without evidence for perforation or underlying GI tract pathology. If the diagnosis of primary peritonitis can be made, these patients are best treated with antimicrobial agents alone and without operation. Because of their severe underlying disease, they are at high risk for poor outcome.

Secondary peritonitis refers to peritoneal infection that occurs secondary to another underlying disease such as bowel perforation. Tertiary peritonitis is a condition first recognized toward the end of the last century and describes patients who continue to have evidence of poorly localized intra-abdominal infection after initial operative and antimicrobial treatment of secondary infection. At subsequent interventions, these patients tend to have evidence of diffuse inflammation without bowel perforation, and cultures return a variety of bacteria that are not common pathogens in the peritoneum such as coagulase-negative staphylococci, *Candida* sp., enterococcus, and *Pseudomonas* sp.⁵³ The categorization of secondary intra-abdominal infection can also be divided into spontaneous infection, those cases arising from underlying disease, and postoperative infection, occurring after operative intervention or other procedures or trauma. Recent series show that approximately 66% of intra-abdominal infections are spontaneous and 34% are postoperative.⁵²

The diagnosis of intra-abdominal infection is almost always first suggested by abdominal pain. This supplemented with a directed history and an exam demonstrating abdominal tenderness strengthens the case. Fever and elevated WBC count are often present, but early cases of appendicitis and diverticulitis will sometimes present with normal temperature and/or WBC count. In patients with diffuse peritonitis such as follows freely perforated bowel or ulcer, the diagnosis is usually made by clinical examination, and this can be followed by resuscitation and operative management without additional sophisticated studies. With abscess, however, the clinical picture is often less straightforward and the addition of cross-sectional imaging techniques, particularly CT scanning, can be very helpful, whereas radionuclide scans have limited usefulness in the diagnosis of intra-abdominal abscess.

Treatment: Source Control

The treatment of intra-abdominal infection always involves the combination of both source control and antimicrobial agents. Diffuse peritonitis involves inflammation and fluid production throughout the peritoneal surface, an area comparable to total body surface area. This is a major hemodynamic challenge and an inflammatory stress to the host organism and must be addressed by attention to circulating blood volume, respiratory status, and other systemic parameters just as in any other critical systemic illness. The fluid requirements of diffuse peritonitis approximate those of a 50% body surface area burn. These fluid shifts accompanied by the cytokine response to peritonitis can easily lead to respiratory and renal failure initially followed by MODS if not treated early and aggressively. Attention to airway, breathing, and circulation must occur simultaneously with antimicrobial management. The systemic disturbance associated with intra-abdominal infection is most readily measured by critical care scores such as the Acute Physiology and Chronic Health Evaluation (APACHE) II score, which has been demonstrated to correlate with mortality and inversely with successful initial treatment of intra-abdominal infection.⁵⁴

Diffuse peritonitis essentially always implies an uncontrolled leak from the GI tract and always mandates operative exploration for source control. If intra-abdominal abscess is diagnosed or suspected, drainage is required, but this can often be accomplished by drains placed percutaneously using the radiologic guidance of fluoroscopy, CT, or ultrasound. Although no prospective trials have been performed comparing open drainage with percutaneous drainage, comparative series suggest that resolution of abscess and mortality are essentially equal between the techniques.⁵⁵ Open drainage of intra-abdominal abscess is usually reserved for those cases in which percutaneous access to the abscess is prevented by overlying viscera. Regardless of the approach to source control, review of multiple series suggests that in approximately one fourth of cases a second effort at source control will be necessary to resolve the infection. This may be another open operation, another percutaneous drain, or conversion from one approach to the other. A subsequent intervention is indicated when the patient fails to improve or worsens following the primary intervention. Ideally, the initial effort at source control should be successful. When the operating surgeon is asked to rate the initial source control procedure, outcome is greatly inferior when he or she is not satisfied with this procedure.^{52,56,57} Regardless, current evidence suggests that second operations should only be pursued in the presence of clinical or radiographic evidence that the original infection has not resolved or that another infection has developed. Mandatory or scheduled relaparotomies are not helpful except to correct specific known defects such as retained packing after damage control or restoration of intestinal continuity that could not be completed at the original procedure.^{58,59}

Treatment: Antimicrobial Therapy

- 6 The initial antimicrobial treatment of intra-abdominal infection is always empiric. The diagnosis is made clinically, and antimicrobial therapy is started when the diagnosis is made and while the patient is being prepared for the source control procedure. Cultures should be taken in the operating room or radiology suite, but bacterial identification will not be available for at least a day for aerobic and facultative species and for at least 2 days or more for anaerobes. Susceptibility data will not be available for an equivalent amount of time after that. Accordingly, the first 2 to 5 days of treatment are empiric and will be completed without specific susceptibility data. The potential bacterial flora of peritonitis is complex. At least 400 different bacterial species can be identified in the human colon.⁶⁰ Despite this, clinical

microbiology laboratories usually recover only three to five different pathogens from intra-abdominal infections and fewer than 15 species account for 80% to 90% of the isolates in reported series.^{61–64} The clinical findings represent a major simplification of the flora that is the usual contaminating source.

Modern concepts regarding antimicrobial agent choice for intra-abdominal infection come from clinical trials comparing antimicrobial agents and from classic animal experiments demonstrating the basic principles in this field. A mouse peritonitis model with defined bacterial inocula showed that an early bacteremic phase was caused by facultative Enterobacteriaceae, primarily *Escherichia coli*, and a late abscess phase was dependent on anaerobes, especially *Bacteroides fragilis*.^{65,66} Antimicrobial agents active against Enterobacteriaceae prevented early mortality, and agents active against the anaerobes prevented late abscess formation. Clinical trials in humans have demonstrated that when antimicrobial regimens are compared, most demonstrate equivalence when both regimens have good activity against both anaerobes and Enterobacteriaceae. A smaller number of trials have demonstrated a clinically and statistically significant difference between antimicrobial regimens and have confirmed that in humans it is important to have coverage against Enterobacteriaceae and against anaerobes.

A number of observational studies have found a strong correlation between the presence of one or more organisms resistant to the antimicrobial agents being used and clinical failure.^{63,67–69} One pathogen that has frequently been correlated with failure is *Enterococcus*, a common enteric organism.⁷⁰ However, no prospective trial has demonstrated a superior result for a regimen that has activity against enterococci when compared with one that does not. In addition, patients who have been hospitalized before the onset of intra-abdominal infection or who develop postoperative intra-abdominal infection have an increased risk of resistant organisms. Despite this, no prospective trial has demonstrated an advantage for a more comprehensive, or “broad spectrum,” regimen for such patients.^{67,71} For these reasons, a consensus has developed that an empiric antimicrobial regimen for the treatment of peritonitis should have broad activity against aerobic and facultative gram-negative bacilli and against enteric anaerobes. The regimen should not be completely inactive against *Staphylococcus* and *Streptococcus* sp. Single and combination antimicrobial regimens that have these characteristics and have been tested in prospective trials are listed in Table 7.6.^{72,73} For some patients it may be helpful for the regimen to have activity against *Pseudomonas aeruginosa* and against *Enterococcus* sp., but accurate criteria for choosing such patients are lacking. A joint Surgical Infection Society and Infectious Diseases Society of America committee has concluded that it is reasonable, based on retrospective series and expert opinion, to provide agents with activity against *Enterococcus* and, in general, antibiotic combinations with broader spectra of activity for patients at high risk of failure due to the severity of physiologic disturbance at presentation and/or acquisition of the infection in a health care setting.^{72–74}

NECROTIZING SOFT TISSUE INFECTIONS

Necrotizing soft tissue infection refers to a spectrum of surgical infections that involve tissue necrosis but are not localized or walled off as abscesses are. These include clostridial infections, which are rare, and nonclostridial infections. Historically, a great variety of labels have been applied to the nonclostridial infections, and in some cases attempts are made to distinguish one from another (Table 7.7).⁷⁵ However, these

- Piperacillin/tazobactam

Combination regimens

- Cefepime, ceftazidime, ciprofloxacin, or levofloxacin plus metronidazole

7 conditions have more in common than the small differences recorded. All present with external signs at the skin level that are far less extensive than the underlying infection, and thus the potential for late diagnosis and treatment. Also, all possess the potential for major tissue loss, significant morbidity, and high mortality. Differences that have been stressed include the pathogen (β -hemolytic *Streptococcus* or CA-MRSA vs. mixed infection), the location (perineum vs. other location), and depth of involvement (involving only superficial tissues vs. muscle also involved). The most common term applied is necrotizing fasciitis, but in most cases the involvement is limited to skin and subcutaneous tissue, and the deeper muscular aponeurosis is not involved. Deeper tissues tend to be involved when the original injury (or operation) breached those areas (e.g., intramuscular hematoma). Necrotizing infection of the abdominal wall can occur after abdominal operations involving bowel entry or treatment of intra-abdominal infection, and the risk is increased when the patient is hemodynamically unstable or when the abdominal wall is closed under tension, causing ischemia in the wound.

TABLE 7.7 CLASSIFICATION**TERMS APPLIED TO SIMILAR NECROTIZING SOFT TISSUE INFECTIONS**

- Gangrenous erysipelas
- Necrotizing erysipelas

- Necrotizing fasciitis
- Necrotizing cellulitis
- Fournier gangrene

Adapted from Dellinger EP. Necrotizing soft-tissue infections. In: Davis JM, Shires GT, eds. *Principles and Management of Surgical Infections*. Philadelphia, PA: J.B. Lippincott; 1991:23–39.

Histotoxic clostridial infections or myonecrosis, commonly called “gas gangrene,” are less common than the nonclostridial infections, which are less likely to but still frequently contain gas due to microbial metabolism. Toxins, produced when clostridia grow in anaerobic conditions, kill muscle and inhibit neutrophil chemotaxis, thus facilitating the spread of infection and systemic toxicity.^{76,77} The most common clostridial organism is *Clostridium perfringens*, followed by *Clostridium novyi*, *Clostridium septicum*, and *Clostridium sordelli*. Although nearly all cases of myonecrosis originate in a traumatic wound, *C. septicum* is capable of causing spontaneous myonecrosis if it gains access to the body through compromised bowel mucosa, which can occur with GI malignancies, such as colon cancer, or during chemotherapy for other malignancies.⁷⁸

Diagnosis

The most important aspect for effective treatment of necrotizing soft tissue infections is early diagnosis. Delay in diagnosis affects outcome adversely. The following physical signs are strongly suggestive of necrotizing infection and merit exploration of the wound in the operating room: any skin necrosis, crepitus, gas in tissue detected by radiologic examination, bullae, or ecchymosis. Other suggestive criteria include marked, or “woody,” edema beyond the area of inflammation or progression of the infection despite apparently appropriate antimicrobial therapy. Although necrotizing soft tissue infections have a reputation for progressing very rapidly, and many do, leading to potential early death, they can also be more indolent and simply persist until diagnosed and debrided.⁷⁹

The diagnostic significance of infection-associated gas is worth an explanation. When aerobic and facultative bacteria are able to use oxidative metabolic pathways, they produce CO₂ as do mammals. CO₂ is highly soluble and is readily carried away by blood flow in perfused tissue. However, when facultative and anaerobic bacteria are forced to use nonoxidative metabolic pathways, they rely on fermentation, denitrification, or deamination. These processes produce nitrogen and hydrogen, which are relatively insoluble and accumulate in the surrounding tissue. Thus, the presence of gas in tissue with infection implies anaerobic metabolism, which is incompatible with living host tissue. This implies that the infection is in non-perfused, dead tissue and requires débridement or drainage.

The persistent difficulty of diagnosis using signs and symptoms has led clinicians to search for other aids to diagnosis. Multiple reports examining the role of ultrasound, CT scans, and magnetic resonance imaging suggest that these techniques have increased sensitivity for detecting abnormalities in affected tissues but are not specific and frequently are unhelpful in distinguishing between soft tissue infections that require operative intervention from those that do not.^{79,80} In addition, biopsy and frozen section examination of affected tissues have been suggested.⁸¹ However, if enough suspicion exists to do a biopsy, most experienced surgeons can recognize the extent of the process and need for débridement visually when the incision is made.⁷⁹

Treatment

Operative management of these infections requires exposure of all affected tissue. This usually necessitates incision through uninvolved skin for a significant distance. Necrotic tissue should be débrided, and involved areas must be exposed, but this does not necessarily require excision of overlying tissues unless they are rendered ischemic by the incisions. Careful planning of incisions should be able to avoid this in most cases. On an extremity, amputation may be required for a clostridial infection, and, although this is uncommon for nonclostridial soft tissue infections, amputation may still be lifesaving and should not be delayed if indicated. Intraoperatively, lack

of muscular contraction in response to electrical stimulation, using cautery, is frequently used to identify dying or dead muscle requiring more extensive débridement. All patients who require operative intervention for a necrotizing soft tissue infection should be scheduled for a second look in the operating room during the next 24 to 48 hours. Decisions regarding further operative intervention can be made at that time. Large wounds are common, and secondary closure or skin grafts may be required after the infection is completely resolved.

Antimicrobial treatment is initially empiric and must be directed against a presumed mixed flora or aerobic and anaerobic pathogens. The choice of agents is essentially the same as for intra-abdominal infection. Initially, high-dose penicillin, gentamicin, and clindamycin are frequently implemented. There is suggestive evidence from animal experiments that high-dose clindamycin, by binding to RNA in the bacteria, may reduce toxin formation by clostridial species and by toxin-producing streptococci and staphylococci.⁸² As with other severe infections, patients with necrotizing soft tissue infections have a marked systemic response and require attention to fluid resuscitation, gas exchange, and renal function.

SEPSIS, SHOCK, AND MULTIPLE ORGAN DYSFUNCTION

A severe systemic response to infection including hemodynamic instability and progression to multiple organ dysfunction can occur after either medical or surgical infections. They can occur after either gram-positive or gram-negative infections but appear to be more common with gram-negative infections and are often triggered by a complex systemic host response to lipopolysaccharide (LPS). Within the context of surgical infections, the best outcome for a patient results from prompt diagnosis and treatment of infections to prevent the onset of sepsis. A number of studies show that early, aggressive correction of physiologic abnormalities seen in early sepsis⁸³ along with prompt aggressive treatment of the infection itself, both with antimicrobial agents and source control,^{84,85} results in the best outcome. Currently, the only additional medical treatment with demonstrated benefit is the administration of activated protein C (drotrecogin alfa) to patients who fit the entry criteria for this trial with sepsis and concomitant organ dysfunction in more than one organ.¹ The risk of increased bleeding complications must be balanced against potential benefits, particularly following recent surgical procedures.

OTHER NOSOCOMIAL INFECTIONS IN SURGICAL PATIENTS

Surgical patients are also susceptible to a number of nonsurgical nosocomial infections during hospitalization. The appropriate care of these patients demands an understanding of the prevention and treatment of these infections.

Catheter-related Bloodstream Infections

Although both peripheral venous and arterial catheters and central venous catheters can be infected, diagnosis is often easier with peripheral catheters, and serious bloodstream infections are more common with central catheters. One of the first principles in preventing these infections is to restrict the use of catheters and to ask each day whether the patient actually needs the catheters that are in place. Another important element of prevention is the insertion technique, especially for central catheters. Although full barrier precautions with wide draping and use of glove, gown, hat, and mask by the inserting physician results in lower infection rates,⁸⁶ this is not always followed. An institu-

tional education program to emphasize the importance of insertion technique has been shown to lower infection rates.⁸⁷ Skin preparation with a chlorhexidine solution results in lower infection rates than preparation with povidone-iodine solutions.⁸⁸ All intravascular devices are susceptible to infection, and the risk increases the longer the catheter is in place. However, changing central lines on a particular schedule does not decrease infection risk.^{89,90} The final risk is related to the number of days that any catheter is in place. Subclavian central venous catheters have a lower risk of infection than internal jugular catheters. Recommendations for the use of antimicrobial-coated catheters are not well established because one must balance the risk of line infection against the risk of additional antimicrobial exposure to the patient and to the environment. When the local rate of infection is high, they are probably justified.⁹⁰ The single most impressive effort in reducing central line-associated infections has been a program that “bundles” all of these components together, uses a checklist, and empowers all members of the medical/surgical team to take responsibility for adherence to the bundle.⁹¹

The diagnosis of catheter-related bloodstream infection is made by isolating the same organism from the bloodstream and from a semiquantitative culture of the catheter tip. To make a diagnosis of catheter-related bloodstream infection without removing the catheter, draw simultaneous cultures through the line and from a different peripheral source. A line infection is indicated when the quantitative culture of the line is equal or greater than five times the peripheral quantity or when the line culture turns positive 2 hours or more before the peripheral culture. When the diagnosis is made, the catheter should be removed. Bacteremia should be treated by a specific antimicrobial agent and, for *S. aureus*, gram-negative rods, or fungi, should be continued for 10 to 14 days.⁹² For coagulase-negative staphylococci, the most common pathogen, duration of treatment can be limited to the period of systemic response after removal of the catheter.

Pneumonia

Pneumonia is less common than SSI and UTI on surgical services but when it occurs is a major source of morbidity and mortality. Prevention of postoperative pneumonia is best accomplished by policies and procedures that emphasize the early extubation of ventilated patients, the use of noninvasive positive-pressure ventilation when feasible, and elevation of the head of the bed for ventilated patients. Diagnosis can be made by physical examination and chest radiograph in the spontaneously breathing postoperative patient. The diagnosis can be much more challenging in the ventilated ICU patient. These patients often have abnormal chest films and physical findings as well as fever and leukocytosis in the absence of pneumonia. In addition, all patients with an endotracheal tube for more than a few days are likely to have bacteria in tracheal aspirates independent of infection. Overtreatment of suspected infection is common, and restriction of treatment for patients without demonstrated pneumonia improves outcome.⁹³ On the other hand, delayed, specific treatment of true infection increases mortality.^{94,95} For this reason, procedures that produce a more specific diagnosis of pneumonia and that help to rule out the diagnosis when pneumonia is not present, such as bronchoalveolar lavage and protected specimen brush cultures, have an important role in the care of ventilated ICU patients.^{96–98} Cultures of expectorated sputum or of simple endotracheal aspirates are very nonspecific and of little use in diagnosing pneumonia. When pneumonia is diagnosed, treatment duration should be limited. Usually 7 to 8 days is sufficient.⁹⁹

Urinary Tract Infection

The most common etiologic agent of UTI in hospitalized patients is the indwelling bladder catheter. Many surgical patients have

urinary catheters placed in the operating room. A primary preventive measure for UTI is to use urinary catheters only when actually necessary due to the location of the operative procedure or the length and complexity of the operation. When a catheter is required it should be removed as soon as possible, often at the end of the operative procedure or on the first post-operative day. When a catheter must be left in place, a closed system should always be used. The risk of UTI doubles on any day when the integrity of a closed system is violated.

In a patient without a catheter, the diagnosis of UTI is traditionally made when a quantitative culture shows greater than 10^5 organisms per milliliter of urine. In patients with catheters, much lower colony counts may represent true infection. Attempts to clear bacteriuria when the catheter is in place usually fail. If the patient is symptomatic, specific antimicrobial treatment should be followed by a catheter change. If the patient is not symptomatic, specific antimicrobial treatment should be given after the catheter has been removed.

PATHOGENS

As noted in the beginning of this chapter, most surgical infections are caused by endogenous microorganisms that gain access to the body after violation of an epithelial barrier. Specific pathogens are identified through culture in the microbiology laboratory, but earlier information can be obtained through examination of a Gram-stained smear of material taken from the infected site. Gram-positive cocci are very commonly found in soft tissue infections and can represent *Staphylococcus* sp., either *S. aureus* or coagulase-negative staphylococci, or streptococcal species. Coagulase-negative staphylococci are the most common pathogens found in catheter-related bloodstream infections but cause serious infections in other locations rarely. *S. aureus* possess virulence characteristics that enable them to invade healthy tissues and form abscesses and are usually significant when recovered. Extensive use of β -lactam antibiotics has led to the emergence of MRSA in many areas, and recently some strains of vancomycin-intermediate *S. aureus* (VISA) and vancomycin-resistant *S. aureus* (VRSA) strains have emerged. In the first decade of the 21st century a new strain of MRSA has become common in the community in patients not recently exposed to the health care system. This is called community-acquired MRSA and is frequently characterized by a new virulence feature, the Panton-Valentin leucocidin that appears to stimulate more tissue necrosis. This organism has been associated with necrotizing soft tissue infections similar to those previously only associated with β -hemolytic streptococci.

β -Hemolytic streptococci, especially from group A, have significant virulence properties that allow them to invade uninjured or minimally injured tissues to cause severe soft tissue infections as previously discussed in the section on necrotizing soft tissue infections. They are uncommon surgical pathogens otherwise. Group D streptococci, or enterococci, are frequently recovered from intra-abdominal infections, but studies fail to demonstrate superior outcomes when antimicrobial regimens are directed toward enterococci. However, this species can clearly cause severe disease in immune-compromised patients, especially liver transplant patients. In this setting the occurrence of vancomycin-resistant enterococci (VRE) in recent years has presented a very difficult treatment challenge.

Facultative gram-negative rods, which can grow in either aerobic or anaerobic environments, are commonly associated with surgical infections, especially those arising from intra-abdominal sources. These include the familiar genera *Escherichia*, *Proteus*, *Klebsiella*, *Enterobacter*, *Morganella*, *Providencia*, and *Serratia*. These pathogens are most commonly treated with advanced-generation cephalosporins, expanded-spectrum penicillins, carbapenems, or fluoroquinolones. In recent years, a number of these pathogens have developed extended-spectrum β -lactam enzymes (ESBLs) capable of inactivating even third-generation

cephalosporins. While these are more common outside of the United States, they are also found in the United States and have increased in recent years. Currently, carbapenem antibiotics are considered the antibiotic of choice for these organisms. An even newer resistance mechanism, *Klebsiella pneumoniae* carbapenemase (KPC enzymes), has led to ESBL pathogens that are also resistant to the carbapenem antibiotics. In these cases only tigecycline; the old, relatively toxic antibiotics polymyxin B and E (colistin); and sometimes aminoglycosides have activity. Bacteria that are resistant to three of the following classes, β -lactams (including penicillins, cephalosporins, and monobactams), carbapenems, fluoroquinolones, and aminoglycosides, are termed multidrug-resistant (MDR) organisms.^{100,101} Obligate aerobic gram-negative rods encountered in surgical patients include *Pseudomonas* sp. and *Acinetobacter* sp. These are most commonly found in the respiratory tract but can also occur in the abdomen. These pathogens often exhibit an even higher degree of antimicrobial resistance than the facultative gram-negative rods.

Anaerobic bacteria are the most common inhabitants of the GI tract in humans and cause significant disease in intra-abdominal infections, but they are not represented in infections proportional to their density in the bowel. The most common isolates are members of the *Bacteroides* genus, especially *B. fragilis* and *Bacteroides thetaiotaomicron*. The most effective antibiotics against these organisms are metronidazole, the carbapenems, and advanced-generation penicillins combined with a β -lactam inhibitor. Moxifloxacin and tigecycline also have activity against the common anaerobes. The anaerobic cocci are also susceptible to the same antibiotics. *Clostridium* sp., as noted in the section on necrotizing soft tissue infections, are most important in that setting. When anaerobes are recovered from a surgical infection or from the bloodstream, this means that bacteria are growing in the body in an anaerobic environment. These are always surgical infections and require source control in addition to antimicrobial treatment.

Fungi, most commonly *Candida* sp., are rarely primary causative agents in surgical infections. However, they are often secondary pathogens, overgrowing on skin and the gut under the influence of broad-spectrum antibacterial therapy. In this setting they become important opportunistic invaders. The most common strain found is *Candida albicans*. Most *Candida* infections are currently treated with fluconazole, but increasing use of this agent tends to provide pressure to increase the presence of resistant strains such as *Candida glabrata* or *Candida krusei*. In these cases, treatment with voriconazole, caspofungin, anidulafungin, micafungin, or amphotericin may be required.

Viruses do not cause surgical infections. Surgical patients are most susceptible to viral infection as a result of blood transfusion, which may transmit hepatitis B, hepatitis C, or the human immunodeficiency virus (HIV). Recent advances in nucleic acid detection technology have rendered the blood supply in the United States increasingly safe so that the current risk for transmission of any of these agents by transfusion is less than 1 in 2 million.¹⁰² Transplant patients are susceptible to a number of viral infections due to their immune-compromised state, especially cytomegalovirus.

ANTIMICROBIAL AGENTS

Antimicrobial agents are used in combination with source control and other treatment modalities to prevent or resolve surgical infections. The goal should be to use these agents when they are required and to withhold them when they are not. Overuse of antimicrobial agents contributes to bacterial resistance and limits their effectiveness when they are needed. They should be used in a manner that ensures therapeutic levels at the site of infection for the appropriate duration. Pharmacodynamic principles of antibiotic use differ for different classes of drugs. The factors that go into an antibiotic's effectiveness include its minimal

inhibitory concentration (MIC) for a particular pathogen, its half-life and mode of elimination from the body, and its mechanism of action.^{103,104} β -Lactam antibiotics such as penicillins and cephalosporins bind to penicillin-binding proteins (PBPs) in the bacterial cell wall and inhibit bacterial cell wall synthesis. Once drug levels are achieved that are well above MIC, the rate of bacterial killing does not increase with higher drug levels. Their effectiveness depends on the percent of time during therapy that the drug levels exceed the MIC at the site of infection. Thus, a dose and time of administration that achieves levels above MIC for more than 50% of the time between doses will provide optimal therapy. This favors drugs with long half-lives or continuous administration of drugs with shorter half-lives. Time above MIC can also be prolonged with intermittent dos-

ing if infusions are prolonged for 1 to 2 hours. Alternatively, aminoglycosides kill by inhibiting microbial protein synthesis, and higher levels of drug above the MIC kill bacteria more rapidly. In addition, these drugs exhibit a “postantibiotic effect” in which bacteria do not begin to grow again for a time after the drug levels have fallen below the MIC. This has led to the once-daily administration of aminoglycoside antibiotics, which achieve very high serum levels shortly after administration and take advantage of the postantibiotic effect after serum levels have fallen. In addition, renal toxicity of the drugs is equal or less with once-daily administration compared with three-times-daily administration, which was the former practice. For quinolones, the best results correlate with the ratio between the area under the curve (AUC) when time is graphed

TABLE 7.8

CLASSIFICATION

ANTIBIOTICS

Penicillin class	Carbapenems
<i>The original</i>	Imipenem/cilastatin
Penicillin G	Meropenem
<i>Antistaphylococcal</i>	Ertapenem
Methicillin	Doripenem
Nafcillin	Fluoroquinolones
Oxacillin	Ciprofloxacin
<i>Limited gram-negative activity</i>	Levofloxacin
Ampicillin	Gatifloxacin
Amoxicillin	Moxifloxacin
<i>Broader gram-negative activity</i>	Aminoglycosides
Carbenicillin	Gentamicin
Ticarcillin	Tobramycin
Piperacillin	Amikacin
<i>β-Lactamase inhibitor combinations</i>	Netilmicin
Ampicillin/sulbactam	Various antianaerobic drugs
Amoxicillin/clavulanate	Chloramphenicol
Ticarcillin/clavulanate	Clindamycin
Piperacillin/tazobactam	Metronidazole
Cephalosporin class	Antimicrobials with activity against MRSA
<i>First generation</i>	Vancomycin
Cephalothin	Quinupristin/dalfopristin
Cefazolin	Linezolid
Cephalexin	Daptomycin
Cephadrine	Tigecycline
<i>Second generation</i>	Antifungal drugs
Cefuroxime	Amphotericin
Cefoxitin	Fluconazole
Cefmetazole	Voriconazole
Cefotetan	Caspofungin
<i>Third generation</i>	Anidulafungin
Cefotaxime	Micafungin
Ceftizoxime	
Ceftriaxone	
Cefoperazone	
Ceftazidime	
Cefepime	

MRSA, methicillin-resistant *Staphylococcus aureus*.

against serum concentration in mg/L. A ratio of AUC/MIC greater than 125 correlates with clinical success.

When antimicrobial agents are used to treat an infection, response to treatment should be evaluated in a regular and ongoing schedule. If improvement is not evident within 2 to 3 days of treatment, the situation should be assessed and an explanation sought. These questions should be asked: Was the original source control adequate? Has a complication of the source control procedure occurred? Has a superinfection developed? Is enough of the proper drug being given in an appropriate manner? The wrong antibiotic is not the most common cause of failure in treating a surgical infection.

Once the patient is improving, one needs to decide how long to continue antimicrobial agents. For most surgical infections, these agents can be stopped when the patient has demonstrated a return to normal temperature and WBC count with improvement in general condition as long as the source control was adequate. There is an absence of objective, prospective data demonstrating the necessary duration of drug treatment. Prolonged antimicrobial agent administration predisposes the patient to superinfections, to colonization with resistant bacteria, and to development of drug adverse reactions and organ damage.

This chapter does not provide a detailed discussion of each antimicrobial drug available. The list is very large and frequently changes. Detailed discussions of indications and doses for individual drugs are available in several reference or online sources, which are updated on a yearly basis. Common examples are the *Sanford Guide*, *The Medical Letter*, and the *Johns Hopkins Division of Infectious Diseases Antibiotic Guide* (<http://hopkins-abxguide.org/>). Table 7.8 lists the classes and individual drugs that are most commonly used by surgeons, grouped by class and antimicrobial activity.

CHAPTER 8 ■ SHOCK

JOSEPH CUSCHIERI

KEY POINTS

- 1 Shock is the clinical syndrome that results from inadequate tissue perfusion from numerous causes: hypovolemic, cardiogenic, extracardiac obstructive, and distributive.
- 2 Hypovolemic shock due to ongoing blood and/or plasma loss leads to progressive cardiovascular deterioration, ultimate hypotension, oliguria, confusion, irreversible cell injury, and death.
- 3 Cardiogenic shock results in decreased tissue perfusion due to intrinsic pump failure.
- 4 Extracardiac obstructive shock attenuates pump function due to external compression of inflow and outflow (tamponade, tension pneumothorax, etc.).
- 5 Septic and traumatic shock, forms of distributive shock, are systemic inflammatory responses to infection or tissue injury with cellular breakdown, producing severe hypotension requiring massive volume resuscitation and high risk of multiple organ failure and death.
- 6 Complications of an episode of shock include ischemia-reperfusion injury from oxidant stress; potential secondary immunosuppression with enhanced nosocomial infection risk; hypothermia and coagulopathy; and multiple organ failure syndrome, including abdominal compartment syndrome.
- 7 Treatment of shock involves aggressive volume resuscitation with control of the underlying etiology and careful monitoring of adequacy of end-organ perfusion to avoid under- and overresuscitation.

- 1 The current accepted concept of shock was first described in 1929 by Walter B. Cannon as inadequate blood flow that results in cellular hypoxia.¹ Persistence of this cellular hypoxia, in turn, results in cellular and organ dysfunction. Although this state can result from a number of causes, it was Blalock who first described hematogenic, neurogenic, cardiogenic, and vasogenic factors that were associated with shock.²

Prior to these concepts, the concept of shock was not understood since the nature and purpose of the heart and circulatory system were either unknown or misunderstood. Galen was the first to explore the purpose of the heart and circulatory system. He proposed that the arteries carried blood, not air, as previously thought, away from the heart. However, he incorrectly believed that arterial blood within the circulatory system subsequently dissolved in the body to release nutrients. Blood returning to the heart was not due to recirculation, but rather was rapidly remanufactured by the liver. Additionally, because much of his dissection work was carried out in frogs, he concluded falsely that the heart had only two chambers and blood passed from the right to left chamber through invisible pores in the septum.³

These conclusions remained unchallenged for nearly 1,500 years until Vesalius, in the 17th century, described dissection of the human body. He demonstrated that blood did not flow directly from the right to left ventricle. Although he provided elaborate drawings of the body's network of blood vessels, he did not anticipate that blood circulated through the body and was unable to discern the heart's purpose. Shortly thereafter, Harvey moved beyond anatomy and studied physiology; he discovered the closed nature of the circulation and concluded that the heart was the main pumping mechanism. Although the microscope had not yet been invented, he proposed the existence of capillaries that connect the arterial and venous system.³

In the following century, military surgeons such as Henri le Dran (1740) noted that injured soldiers left unattended for several hours suddenly deteriorated as if there had been a *secousse* (jolt) to the system, which probably led to use of the word "shock."¹ Surgeons began to notice that even when a wounded extremity was amputated, the physiologic effects of the injury often continued, and shock was increasingly recognized as a distinct systemic syndrome apart from the wound itself.³

Eventually, Cannon and then Blalock described our current concept of shock and its attributed systemic effects. In fact, Blalock was the first to recognize the third-space fluid loss that follows shock resuscitation that is greater than the quantity of initial blood loss.⁴ As a result, therapy began to focus not only on restoring intravascular volume but also on replacing fluid lost to the interstitium with a balanced salt solution. Investigators then became increasingly intrigued by the fact that, at some point, shock becomes irreversible and is no longer responsive to further volume resuscitation. As stated more than 50 years ago by Wiggers, "at a certain stage an adequate circulation cannot be restored by merely filling the system, as one does an automobile radiator."⁵ At some point the wound, infection, cardiac dysfunction, or other initiating event is no longer the primary threat. Other factors sustain the shock state, blood pressure cannot be restored, improvements are only transient, and death occurs shortly thereafter.

The current concept of shock has led to a reclassification into four distinct groups—hypovolemic, cardiogenic, extracardiac obstructive, and distributive—that may occur independent of each other, or more characteristically synergistic with each other.⁶ Early recognition and prompt treatment are essential to modern treatment. If delayed, uncorrected hypovolemia and critical oxygen delivery deficits occur that lead to irreversible shock. However, it is believed that future therapies will move beyond simple recognition and fluid resuscitation, and indices of tissue oxygenation that target the internal machinery of the cell itself will be followed. Thus, investigators are increasingly looking to gain an understanding of the chain of events that occur that lead to organ damage and irreversibility. This chapter describes these events, discusses the therapeutic approaches utilized in current management, and offers a brief perspective on what may lie ahead in the future.

EVALUATION OF SHOCK

Shock is easily recognized by even the most inexperienced caregiver after the compensatory mechanisms have been overcome (Table 8.1). However, it is more difficult to recognize the

TABLE 8.1**SHOCK RECOGNITION**

■ ORGAN SYSTEM	■ SIGN/SYMPTOM	■ CAUSE
CNS	Mental status changes (agitation/anxiety to coma)	Decreased cerebral perfusion
Circulatory		
Cardiac	Tachycardia	Adrenergic stimulation
	Atrial/ventricular dysrhythmias	Coronary ischemia
	Hypotension	Coronary ischemia, right heart failure
Systemic	Hypotension	Decreased SVR, decreased venous return
	Decreased CVP	Hypovolemia
	Increased CVP	Right heart failure
Respiratory	Tachypnea	Pulmonary edema, sepsis, compensation for metabolic acidosis
	Cyanosis	Hypoxia
Renal	Oliguria	Decreased perfusion, afferent arteriolar vasoconstriction
Skin	Cool, clammy	Vasoconstriction
	Warm, dry	Vasodilation

CNS, central nervous system; CVP, central venous pressure; SVR, systemic vascular resistance.

patient in compensated shock, who presents with vital signs that are almost normal. It is critically important to the patient's ultimate outcome that recognition and treatment of shock occur before decompensation. The clinical assessment must be guided by the knowledge that the severity of symptoms and signs of shock vary between patients and the degree of the type of shock present. The patient is evaluated based on clinical appearance, hemodynamic measurements, physiologic responses, and biochemical analyses.

Early during various shock states, vasoconstriction frequently causes the skin to be cool, with poor capillary refill. However, this must be contrasted to shock states induced by either neurogenic or septic states in which vasodilation is present causing the skin to be warm, with good capillary refill. Common to the various shock states is the presence of hyperventilation, a compensatory response due to progressive metabolic acidosis. As shock progresses, mental status changes occur, and decreased cerebral blood flow and increased catecholamine stimulation may lead to anxiety and restlessness. With continued shock, lethargy may result. True coma, however, seldom results due to shock alone, unless coincident complete cardiovascular collapse occurs, and is usually associated with other conditions such as direct brain injury or severe hypoxia.⁷

The hemodynamic assessment should include evaluation of the rate and character of the pulse, the blood pressure, and, in some cases, the central venous pressure (CVP) and pulmonary artery pressure.⁸ Tachycardia is a normal response to volume loss but also to pain, anxiety, and fear, all of which are commonly present. Assessment of the pulse (full and strong or weak and thready) may be helpful in determining the proper diagnosis. Because of the body's ability to compensate for hypovolemia, changes in blood pressure do not occur reliably until 20% to 30% of blood volume has been lost. However, the pulse pressure usually narrows, even in compensated shock, because of the effects of vasoconstriction on the diastolic blood pressure. Importantly, the CVP reflects the adequacy of and not the true blood volume, and the state of the venous tone. Changes in CVP in response to treatment or from

continuing hemorrhage are more revealing than a solitary measurement.

An indirect but extremely valuable measure of perfusion and volume status is urine output. A urinary catheter should be inserted in every patient being evaluated for shock. Hourly urine output should be 0.5 to 1 mL/kg for adult patients, at least 1 mL/kg for most pediatric patients, and 1 to 2 mL/kg for patients younger than 2 years of age. Lack of adequate appropriate urine output in the setting of previous normal kidney function should cause the caregiver to be highly concerned about the continued presence of inadequate perfusion and cellular hypoxia.

Although each of the physical examination components are important in the identification of shock, used alone these factors can lead to a potential underdiagnosis of compensated shock due to the robust ability of the human body to compensate to various degrees. As a result, biochemical markers have been added as a means to identify shock in its early stages. Biochemical analysis of shock is based on the shift from aerobic to anaerobic metabolism in underperfused tissues. Increased lactate production is associated with tissue hypoperfusion. In addition, lactate appears to be prognostic in several different shock states including hypovolemic, septic, and cardiogenic.⁹ Resuscitation of shock results in a decrease in serum lactate levels, and the time required to normalize serum lactate levels appears to be an important prognostic factor for survival.^{10,11}

Another biochemical marker of shock and resuscitation is the base deficit. This is defined as the amount of a fixed base (or acid) that must be added to an aliquot of blood to restore the pH to 7.40. Base deficit values have been categorized as normal (2 to -2), mild (-3 to -5), moderate (-6 to -9), and severe (>-10). Changes in base deficit toward normal with volume infusion can be used to judge the efficacy of resuscitation.¹²⁻¹⁴ Further, base deficit has been shown to be superior to pH values in assessing the normalization of acidosis after shock resuscitation, and the time required for normalization of base deficit has perhaps even greater prognostic significance than that for lactate.^{12,15}

These biochemical changes associated with the hypoperfusion of shock occur even with compensation. Because of the potential difficulties in diagnosing compensated shock, an arterial and/or venous blood gas analysis including base deficit and lactate should be obtained for every patient suspected of being in shock. Additionally, any patient with a lactate of ≥ 4 mmol/L or base deficit of ≥ 6 mEq/L should be considered to be in shock until proven otherwise.^{13,16,17}

Although each of these factors can be used to characterize shock, no single measurement has been determined to be optimal or when used singly to be always accurate for identification and treatment of shock. Currently, other measurements are being investigated that demonstrate promise. These markers include measurements of central and mixed venous oxygen saturations, end-diastolic cardiac volume indices, and specific noninvasive end-organ tissue oxygen saturations.^{18–23}

TYPES OF SHOCK

Although several different classifications for shock have been described, the most currently widely accepted classification of shock was proposed by Weil and Shubin in 1971.⁶ This classification divides the shock syndrome into four distinct categories (Table 8.2). Despite this separation, however, there is considerable overlap between the categories, with some patients presenting with more than one factor at the same time. Given this overlap, it is helpful to evaluate the hemodynamic pattern in order to elucidate the etiology and manage the patient (Table 8.3).

Hypovolemic Shock

- 2 Hypovolemic shock is the form of shock most commonly encountered in surgical practice (Table 8.2). The essential feature is a reduction in intravascular volume to a level that prevents the heart from being able to pump sufficient blood to vital organ systems. Substantial blood ($>20\%$ circulating volume) or plasma (via soft tissue or enteric sequestration or gastrointestinal, urinary, or insensible losses) losses are required to produce this syndrome.

The signs and symptoms of shock vary with both the severity and duration of blood loss. A review of the Advanced Trauma Life Support classification system of the American College of Surgeons is useful to comprehend the manifestations and physiologic changes associated with hemorrhagic shock in adults.²⁴ Blood volume is estimated at 7% of ideal body weight, or approximately 4,900 mL in a 70-kg patient (Table 8.4).

Class I: Mild hemorrhage, up to 15% of total blood volume. This condition is exemplified by voluntary blood donation. In the supine position, there are no measurable changes in heart or respiratory rates, blood pressure, or pulse pressure. Capillary refill is normal. This degree of hemorrhage requires little or no treatment, and blood volume is restored within 24 hours by transcappillary refill and the other compensatory methods.

Class II: Loss of 15% to 30% of blood volume (800 to 1,500 mL). Clinical symptoms include tachycardia and tachypnea. The systolic blood pressure may be only slightly decreased, especially in the supine position, but the pulse pressure is narrowed (because of the diastolic increase from adrenergic discharge). Urine output is reduced only slightly (20 to 30 mL/h). Mental status changes (e.g., anxiety) are frequently present. Capillary refill is usually delayed. Patients with class II hemorrhage usually can be resuscitated with crystalloid solutions, but some may require blood transfusion.

Class III: Loss of 30% to 40% of blood volume (up to 2,000 mL). Patients with class III hemorrhage present with inadequate

perfusion that is obvious; marked tachycardia and tachypnea; cool, clammy extremities with significantly delayed capillary refill; hypotension; and significant changes in mental status (e.g., confusion, combativeness). Class III hemorrhage represents the smallest volume of blood loss that consistently produces a decrease in systolic blood pressure. The resuscitation of these patients frequently requires blood transfusion in addition to administration of crystalloids.

Class IV: Loss of more than 40% of blood volume (more than 2,000 mL), representing life-threatening hemorrhage. Symptoms include marked tachycardia, a significantly depressed systolic blood pressure, and narrowed pulse pressure or unobtainable diastolic pressure. The mental status is depressed and the skin is cold and pale. Urine output is negligible. These patients require immediate transfusion for resuscitation and frequently require immediate surgical or other (e.g., angiographic embolization) intervention.

In practice, individual susceptibility to blood loss varies greatly and is affected by age, pregnancy, preexisting disease, prescription and nonprescription medications (e.g., beta-blockers), adequacy of compensatory mechanisms, and other factors that are poorly characterized. Presence of these factors should lead the caregiver to consider early use of invasive monitoring as an adjunct to appropriate fluid resuscitation.

Hypovolemia due to plasma losses may also lead to hypovolemic shock. The clinical findings of hemorrhagic shock are typically present, but significant differences do exist. Hemoconcentration, elevated blood urea nitrogen (BUN) and creatinine, and hypernatremia are typical of acute plasma and/or free water losses and are not necessarily present in other forms of shock. Appropriate evaluation of preload and urine output should be followed, with specific considerations for unique electrolyte abnormalities associated with specific plasma and fluid losses (e.g., gastric vs. colonic losses).

Cardiogenic Shock

- 3 The clinical definition of cardiogenic shock is decreased cardiac output with tissue hypoperfusion, despite presence of adequate intravascular volume. It is caused by a primary problem with the cardiac muscle, electrical conduction system, or valves. The most common cause is anterior wall myocardial infarction, although in surgical patients it is often precipitated by pulmonary embolus, myocardial contusion, or pulmonary hypertension.

Distinguishing cardiogenic shock from other shock etiologies is occasionally difficult. It is not uncommon to see combined cardiogenic and traumatic shock in the elderly patient, with one often being the precipitating event for the other. The hallmarks of the hemodynamic and neuroendocrine response to systemic hypoperfusion from other causes are also typical of cardiogenic shock. Eliciting a history of preexisting cardiac disease, and physical findings such as pulmonary rales, cardiac murmurs, an S3 gallop, and jugular venous distention may be helpful. An electrocardiogram may detect significant ischemia or other pathology. A chest radiograph may reveal bilateral pulmonary infiltrates typical of cardiogenic edema, and cardio-specific serum tests (troponin I, creatine phosphokinase [CPK]) may indicate myocardial damage.

Manifestations of cardiogenic shock develop as a consequence of failure of peripheral perfusion, the associated adrenergic response, and the inability of the heart to accommodate blood returning from the lungs and the periphery. In the absence of sepsis or tissue injury, however, there is not usually an associated increase in the metabolic needs of the peripheral tissues. Sympathetic-mediated constriction of the peripheral vasculature attempts to maintain central blood pressure and perfusion of cerebral and coronary circulations. The clinical

CO, cardiac output; CVP, central venous pressure; MI, myocardial infarction; N, normal; PAOP, pulmonary artery occlusion pressure; SvO₂, mixed venous oxygen saturation; SVR, systemic vascular resistance.

findings of cardiogenic shock may thus be similar to those of hypovolemic shock because both involve induction of the adrenergic response.

Diminished or ineffective contractile activity of the right or left side of the heart allows blood to accumulate in the respective venous circulations. Shock from an acute left ventricular myocardial infarct occurs when more than 40% of the left ventricle is involved and may be present in approximately 20% of Q-wave infarcts.²⁵ Shock from an acute right ventricular myocardial infarct, on the other hand, is rare and only occurs in approximately 10% of all inferior wall infarcts.²⁶ Not only does the diagnosis of each infarct vary, but also the treatment and support vary significantly.

In any patient in shock, especially in those with compromised cardiac function, consideration should be given to the institution of mechanical ventilation. The work of breathing can be considerable, especially for the patient in a state of agitation or distress. Oxygen needs are decreased through intubation and mechanical ventilation. In this manner, the patient can be comfortably sedated with a secure airway; the work of breathing is undertaken by the ventilator, and gas exchange can

be optimized. If there is a tenuous balance between myocardial oxygen needs and availability, the balance can thus be shifted in the patient's favor.

Like other forms of shock, cardiogenic shock tends to be self-perpetuating. Myocardial perfusion depends on the pressure gradient between the coronary artery and the left ventricle and the duration of diastole. Both are compromised by the hypotension and tachycardia that characterizes this condition. High-volume fluid resuscitation, sometimes necessary for treatment of other forms of shock, is poorly tolerated and likely to be detrimental to an individual with the compromised myocardial function of cardiogenic shock.

Extracardiac Obstructive Shock

- 4 A subset of patients with cardiogenic shock do not have intrinsic cardiac disease but have pump failure due to extrinsic compression that limits diastolic filling and cardiac output. Cardiac tamponade, tension pneumothorax, diaphragmatic herniation of abdominal viscera, mediastinal hematoma, and,

TABLE 8.4

CLASSIFICATION OF HEMORRHAGIC SHOCK

	■ CLASS I	■ CLASS II	■ CLASS III	■ CLASS IV
Blood loss (mL)	Up to 750	750–1,500	1,500–2,000	>2,000
Blood loss (%)	Up to 15	15–30	30–40	40
Heart rate	<100	>100	>120	>140
Blood pressure	Normal	Normal	Decreased	Decreased

Respiratory rate	14–20	20–30	30–40	>35
Urine output (mL/h)	>30	20–30	5–15	Minimal
Mental status	Normal	Mildly anxious	Anxious and confused	Confused and lethargic
Fluid replacement	Crystalloid	Crystalloid	Crystalloid and blood	Crystalloid and blood

occasionally, positive-pressure mechanical ventilation may all precipitate cardiogenic shock by exerting constricting pressure on the myocardium. The key to diagnosis and appropriate therapy is the physical examination, supplemented by use of appropriate diagnostic modalities.

The classic physical findings of cardiac tamponade, Beck’s triad, are hypotension, muffled heart sounds, and jugular venous distention. Unfortunately, these nonspecific clinical findings are seldom present together. Elevated jugular venous pressure, noted by either physical examination or measurement of CVP, although not specific for cardiac compression, is usually present. Pulsus paradoxus can be useful for the diagnosis of cardiac tamponade. Although it may be caused by other conditions, it is virtually always present in patients with tamponade.

Given the difficulty in evaluation of these patients, especially in combination with other shock states, early diagnostic evaluation, both invasive and noninvasive, of cardiac function is warranted. Recent guidelines suggest that any patient with concern for primary or secondary cardiac dysfunction should undergo early ultrasound evaluation. This early evaluation not only evaluates the primary cardiac function but also can lead to the early diagnosis and management of secondary causes of cardiac dysfunction including cardiac tamponade and pulmonary embolism.

Distributive Shock

Distributive shock occurs in a state of inappropriate oxygen utilization associated with the systemic inflammatory response syndrome (SIRS). Classically, SIRS is triggered by sepsis, but SIRS is associated with other immune processes including trauma, pancreatitis, and other types of tissue injuries. However, other types of distributive disturbances can occur unrelated to inflammation that may be directly due to loss of vascular tone from spinal cord injury, endocrine dysfunction, or anaphylaxis.

Septic Shock

5 Septic shock is defined as a SIRS response to infection in conjunction with arterial hypotension, despite adequate fluid resuscitation.²⁷ It occurs when bacterial products interact with cells of the immune system, leading to elaboration of mediators that cause circulatory disturbances and direct and indirect cell damage leading to the clinical manifestations of SIRS (Table 8.5).²⁸ Hemodynamic changes are defined as early (warm or hyperdynamic) or late (cold or hypodynamic). These stages are primarily characterized by the degree of ventricular contractility and

peripheral vasomotor impairment present, but can be misclassified if not appropriately evaluated. Early septic shock is distinguished by peripheral vasodilation, flushed and warm extremities, and a compensatory elevation in cardiac output. Although an increase in venous capacitance diminishes venous return to the heart, cardiac output is maintained via tachycardia and the decrease in afterload due to systemic vasodilation.

Late septic shock is characterized by impaired myocardial contractility due to local and systemic release of cardiac depressants, worsening peripheral perfusion, vasoconstriction, extremity mottling, oliguria, and hypotension. Peripheral oxygen utilization may be severely impaired by bacterial toxins, such as lipopolysaccharide (LPS) and the inflammatory products of the host’s own immune response, resulting in metabolic dysfunction and acidosis despite a high systemic oxygen delivery. This inappropriate oxygen utilization and systemic shunting lead not only to confusion regarding the adequacy of resuscitation, but also to progressive cell death. Together, both systemic hypoperfusion and the altered tissue metabolism create a vicious cycle that propagates the inflammatory response initiated in reaction to the initial infectious challenge leading to progressive cellular injury.

Due to both volume deficits and cardiovascular dysfunction, persistent perfusion deficits are common and contribute significantly to multiple organ failure and mortality. In fact, the fluid volume required for treatment may exceed that required for treatment of other forms of shock due to persistent microvascular endothelial capillary leak. As a result of this profound leak, interstitial and total body fluid balances become extreme, leading to the potential development of marked hypoxia and the abdominal compartment syndrome.

Although appropriate early resuscitation and cardiovascular support are essential to the treatment of septic shock, as important are early infection source control and appropriate administration of antimicrobials. In fact, numerous investigators have demonstrated that even a few hours’ delay in initiation of antimicrobial therapy is associated with a significant increase in mortality.²⁹

Traumatic Shock

The major contributor to shock after injury is hypovolemia due to hemorrhage. Even when hemorrhage ceases or is controlled, patients can continue to suffer loss of plasma volume into the interstitium of injured tissues and develop progressive hypovolemic shock. In addition, tissue injury evokes a broader pathophysiologic immunoinflammatory response and a potentially more devastating degree of shock than that produced by hypovolemia alone.

The degree to which direct tissue injury and an inflammatory response participate in the development and progression of traumatic shock distinguishes it from purely hypovolemic shock. Thus, traumatic shock results from direct tissue or bony injury, resulting in not only hypovolemia caused by fluid and blood loss but also an immunologic and neuroendocrine response to tissue destruction and devitalization. This combined insult complicates what might otherwise be straightforward hemorrhagic shock by inducing a systemic response that utilizes many of the inflammatory mediators present in septic shock.³⁰ These mediators propagate and intensify the effects of the initial hypovolemia and make subsequent multiple organ failure far more likely than occurs with hypovolemic shock alone.

Although this condition can lead to increased fluid requirements, common problems associated with this condition such as rhabdomyolysis should be aggressively evaluated and treated with optimal resuscitation.³¹ In addition, common patient characteristics are known to alter traumatic shock resuscitation, in particular, morbid obesity that can result in delayed correction of metabolic acidosis and increased risk for organ dysfunction.³²

TABLE 8.5
SYSTEMIC INFLAMMATORY RESPONSE SYNDROME

Systemic inflammatory response syndrome: The systemic inflammatory response to a variety of severe clinical inflammatory factors is manifested by two or more of the following conditions:
Temperature >38°C or <36°C
Heart rate >90 bpm
Respiratory rate >20 breaths/min or PaCO ₂ <32 mm Hg
WBC count >12,000 cells/mm ³ , <4,000 cells/mm ³ , or >10% immature (band) forms

bpm, beats per minute; PaCO₂, partial pressure of arterial carbon dioxide; WBC, white blood cell count.

Thus, initial management of the seriously injured requires the assurance of an airway, breathing, and circulation; later management requires appropriate volume resuscitation and control of ongoing losses. Control of hemorrhage is a major concern and demands priority over attention to other injuries. After resuscitation and control of volume losses, efforts become necessary to minimize the potentially lethal postshock sequelae, including acute respiratory distress syndrome (ARDS) and multiple organ dysfunction syndrome (MODS).

Neurogenic Shock

Neurogenic shock is defined as failure of the nervous system to provide effective peripheral vascular resistance, resulting in inadequate end-organ perfusion. Warm, flushed, flaccid extremities; paraplegia; confusion; oliguria; and hypotension are the classic clinical findings. Injury to the proximal spinal cord, with interruption of the autonomic sympathetic vasomotor pathways, disrupts basal vasoconstrictor tone to peripheral veins and arterioles. Profound vasodilation of all microvascular beds below the level of cord injury diminishes venous return to the heart, reduces cardiac output, and precipitates hypotension. Injuries at or above the fourth thoracic vertebrae may disrupt sympathetic innervation to the heart, resulting in significant bradycardia and severe decompensation.

Similar to the initial therapy for shock resulting from hypovolemia, treatment of the relative hypovolemia due to vasodilation of neurogenic shock requires intravenous volume resuscitation. Restoration of the pathologically expanded intravascular space improves preload and cardiac output and may reverse hypotension. However, maintenance of adequate hemodynamics often requires vasopressor support in an effort to avoid the administration of excessive fluids. CVP monitoring to assess cardiac preload should be considered as a means of determining adequate and nonexcessive filling pressures, as loss of vasomotor capacity within the pulmonary circulation predisposes these patients to pulmonary edema. As spinal cord injury is often associated with other traumatic injuries, the diagnosis of isolated neurogenic shock must be a process of exclusion.

This condition should not be confused with spinal shock. Spinal shock is defined as a loss of sensation accompanied by motor paralysis with initial loss but gradual recovery of spinal reflexes following spinal cord injury. The reflexes caudal to the spinal cord injury are hyporeflexic or absent, while those rostral are unaffected. No circulatory compromise is associated with this condition; thus, it should not be considered a shock state.

Hypoadrenal Shock

The role of adrenocortical hormones in providing resistance to shock is well recognized. The reduction in effective blood volume and changes in blood chemistry that occur after adrenal ectomy are similar to those of shock and hemorrhage. Adrenalectomized animals have markedly diminished tolerance to both trauma and hypovolemia. Adrenal cortical hormones also play a key role in maintaining normal capillary tone and permeability. In recent years, the concept of functional or relative adrenal insufficiency has received increasing attention as a cause of unrecognized shock and hypoperfusion. Most critically ill patients have elevated cortisol levels, but some have low concentrations in relation to the degree of stress imposed by their disease. Administration of physiologic doses of steroids to correct this insufficiency may result in stabilization of hemodynamics and possible survival benefits.³³ However, the concept of routine administration of physiologic doses of steroids has been questioned and thus routine and indiscriminate use is not recommended.³⁴

Diagnosis of hypoadrenal shock is difficult, as classic signs of Addison disease are absent. The only clinical clues may be

unexplained hypotension and refractory response to high-dose vasopressors. An isolated serum cortisol level is difficult to interpret because the range of values observed in critically ill patients varies considerably. A cortisol level below 15 $\mu\text{g/dL}$ suggests a high likelihood of adrenal insufficiency, whereas a value above 35 $\mu\text{g/dL}$ suggests an adequate renal function.³⁵ The adrenocorticotrophic hormone (ACTH) stimulation test may be used to identify hypoadrenal patients when the diagnosis is unclear, but the utility of this test, particularly with an elevated baseline value, is of questionable utility.

The utility of the ACTH stimulation test is especially questionable in patients with persistent evidence of shock and elevated baseline levels of cortisol above 35 $\mu\text{g/dL}$. These patients actually demonstrate evidence of inadequate systemic cortisol utilization with a significant risk of mortality, and thus may actually benefit from systemic administration of physiologic concentrations of corticosteroids.³⁵

Although hypoadrenal shock may complicate various types of shock, there is conflicting evidence to support the use of supplemental corticosteroids in patients with septic shock if there is biochemical evidence of hypoadrenalism. Thus, supplemental corticosteroids should be used with extreme caution until further evidence is available.^{27,36}

PHYSIOLOGIC RESPONSE TO HYPOVOLEMIA

Common to each shock state is usually an initial decrease in circulating intravascular volume. This reduction is due directly to fluid loss or secondarily to fluid redistribution. This reduction in circulating fluid volume initiates both a rapid and sustained compensatory response. Within minutes, a rapid compensatory response occurs primarily due to adrenergic output. Sustained responses, in contrast, occur slower and result in intravascular fluid reabsorption and renal conservation of water and electrolytes (Algorithm 8.1).

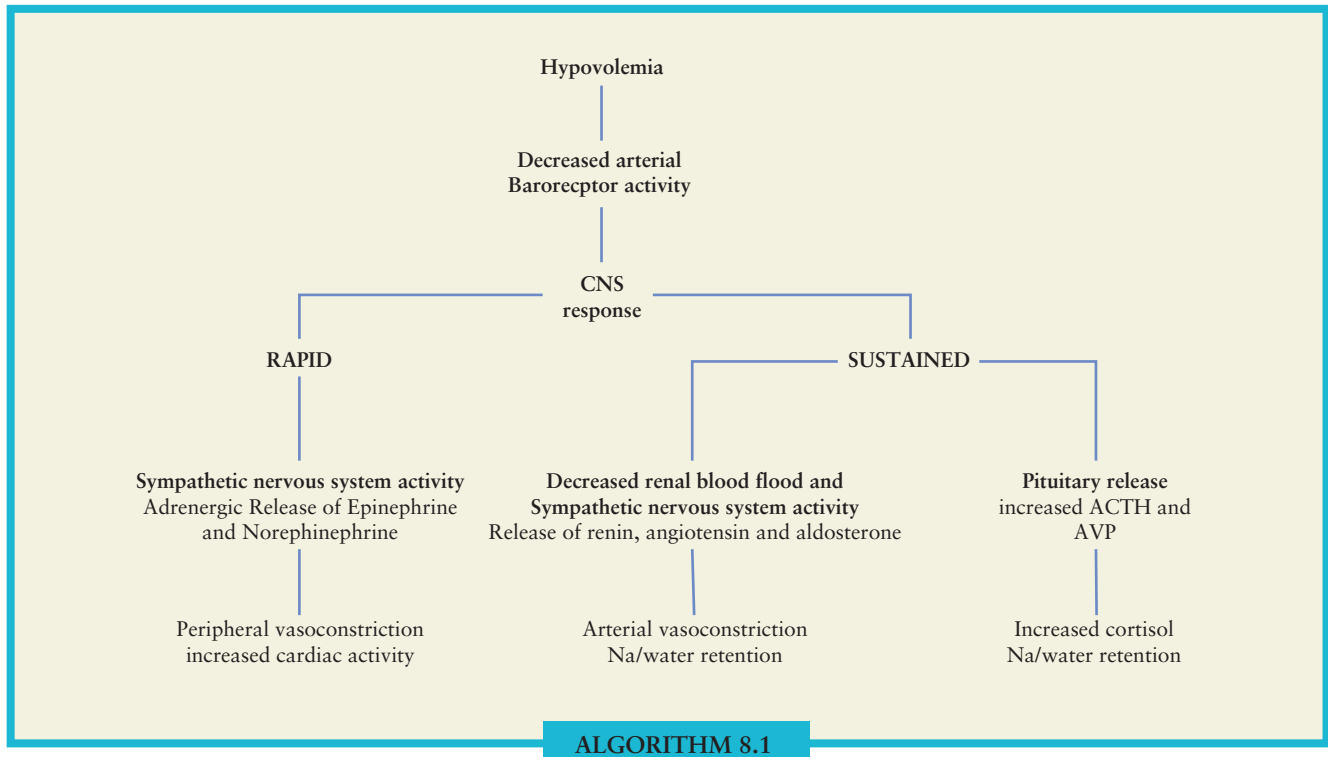

Rapid Response

Hypovolemia results in the initial secretion of epinephrine and norepinephrine from the adrenal gland due to decreased afferent impulses from arterial baroreceptors. Catecholamine release is acute, and limited to the first 24 hours following the onset of hypovolemia. This results in vasoconstriction, tachycardia, and increased myocardial contractility. Adrenergic-induced vasoconstriction of the systemic capacitance of small veins and venules shifts blood back to the central venous circulation, thus increasing right-sided filling pressures. Left-sided filling and pressure are augmented by pulmonary vasoconstriction. Concomitantly, vasoconstriction occurs in the skin, kidneys, and viscera, effectively shunting blood to the heart and brain. Adrenergic-induced vasoconstriction increases cardiac filling and causes increased contractility and reflex tachycardia, all of which combine to increase stroke volume and cardiac output.

Adrenergic-mediated vasoconstriction affects arterioles, pre- and postcapillary sphincters, and small veins and venules. Due to this specific vasoconstriction, decreased hydrostatic pressure distal to the precapillary sphincter occurs that leads to reabsorption of interstitial fluid [water, sodium (Na^+), and chloride (Cl^-)] into the vascular space. This functions to restore circulating blood volume and is known as transcapillary refill.³⁷

Sustained Response

Sustained compensatory responses include the release of vasoactive hormones and fluid shifts from the interstitium and

ALGORITHM 8.1. Neurohormonal response to hypovolemia.

the intracellular space to the intravascular compartment. Decreased renal blood flow, increased adrenergic activity, and compositional changes in tubular fluid lead to the secretion of renin from the juxtaglomerular complex. Renin results in increased formation and release of angiotensin I by the liver. Circulating angiotensin I is rapidly converted to angiotensin II by the lungs and is the most potent known arterial and arteriolar vasoconstrictor. Angiotensin II also stimulates the release of pituitary ACTH. Increased circulating levels of both angiotensin II and ACTH result in increased secretion of aldosterone. As a result, reabsorption of Na^+ in the distal renal tubules in exchange for potassium (K^+) and hydrogen ions occurs.

Additionally, due to hypovolemia and increased serum osmolarity, reduced stimulation of arterial baroreceptors occurs, leading to the release of arginine vasopressin (AVP), also known as antidiuretic hormone (ADH). This hormone not only functions as a potent vasoconstrictor but also causes increased reabsorption of water by increasing water permeability and passive Na^+ transport in the distal renal tubule. The overall net effect of aldosterone and AVP is to decrease glomerular filtration and increase salt and water tubular reabsorption in an effort to replace circulating intravascular volume deficits.

Finally, the increased release of the stress hormones (epinephrine, ACTH, cortisol, and glucagon) leads to glycogenolysis, lipolysis, and protein catabolism, causing a negative nitrogen balance and high extracellular concentration of glucose due to decreased insulin release and resistance. This leads to increased glucose utilization by insulin-independent tissues such as the brain and heart. In addition to glucose, products of anaerobic metabolism from hypoperfused cells accumulate in the extracellular compartment, inducing hyperosmolarity. This extracellular hyperosmolarity draws water from the intracellular space, increasing interstitial osmotic pressure, which in turn drives water, Na^+ , and Cl^- across the capillary endothelium into the vascular space.

ORGAN-SPECIFIC COMPENSATORY RESPONSES TO SHOCK

Cardiac and Microvascular Response

Cardiovascular physiology is profoundly affected by shock (Table 8.3). Reduced stroke volume is caused by an absolute or relative loss of preload. Intrinsic neuroendocrine and renal compensatory responses, along with additional intravenous fluid, are needed to increase ventricular end-diastolic volume. Restoration of adequate preload alone is often sufficient to return cardiac output to levels required to overcome peripheral perfusion deficits. However, some cases are complicated by acquired myocardial contractility derangements. Contractile function under these conditions is less a function of preload and more related to intrinsic myocardial dysfunction.

A defining characteristic of shock is compromise of microvascular perfusion. Far from being a passive conduit, the microvasculature actively participates in the response to shock. Arteriolar vessels are innervated by sympathetic nerves, as are small veins and venules. The vasoconstriction of hypovolemic shock and the vasodilation of septic and neurogenic shock are a result of these autonomic responses. The majority of the circulating blood volume resides in the venous system, and normal physiologic compensation mechanisms rely on this venous blood pool as an autotransfusion reservoir. Collapse of underperfused veins passively propels blood toward the heart, while α -adrenergic venoconstriction actively mobilizes the venous pool. Profound peripheral vasoconstriction via α -adrenergic, vasopressin, angiotensin II, and endothelin-1 stimulation of arteriolar and precapillary smooth muscle sphincters selectively diminishes perfusion to dermal, renal, muscle, and, significantly, splanchnic vascular beds to preserve perfusion of critical central organs, primarily the central nervous system (CNS) and myocardium.³⁸

The capillary endothelial monolayer maintains a semipermeable barrier between the intra- and extraluminal spaces and is compromised by shock.³⁹ Circulating inflammatory mediators and byproducts of infection (LPS, thrombin, tumor necrosis factor alpha [TNF- α], interleukin [IL]-1, nitric oxide, and endothelin-1) generated in response to traumatic or septic shock have been shown to induce and sustain endothelial capillary leak. Although the exact mechanisms of endothelial monolayer dysfunction are unclear, the only available therapies to reverse microvascular decompensation are timely restoration of peripheral perfusion, rapid elimination of infectious and necrotic tissue, and pharmacologic and mechanical support of cardiopulmonary function.^{40,41}

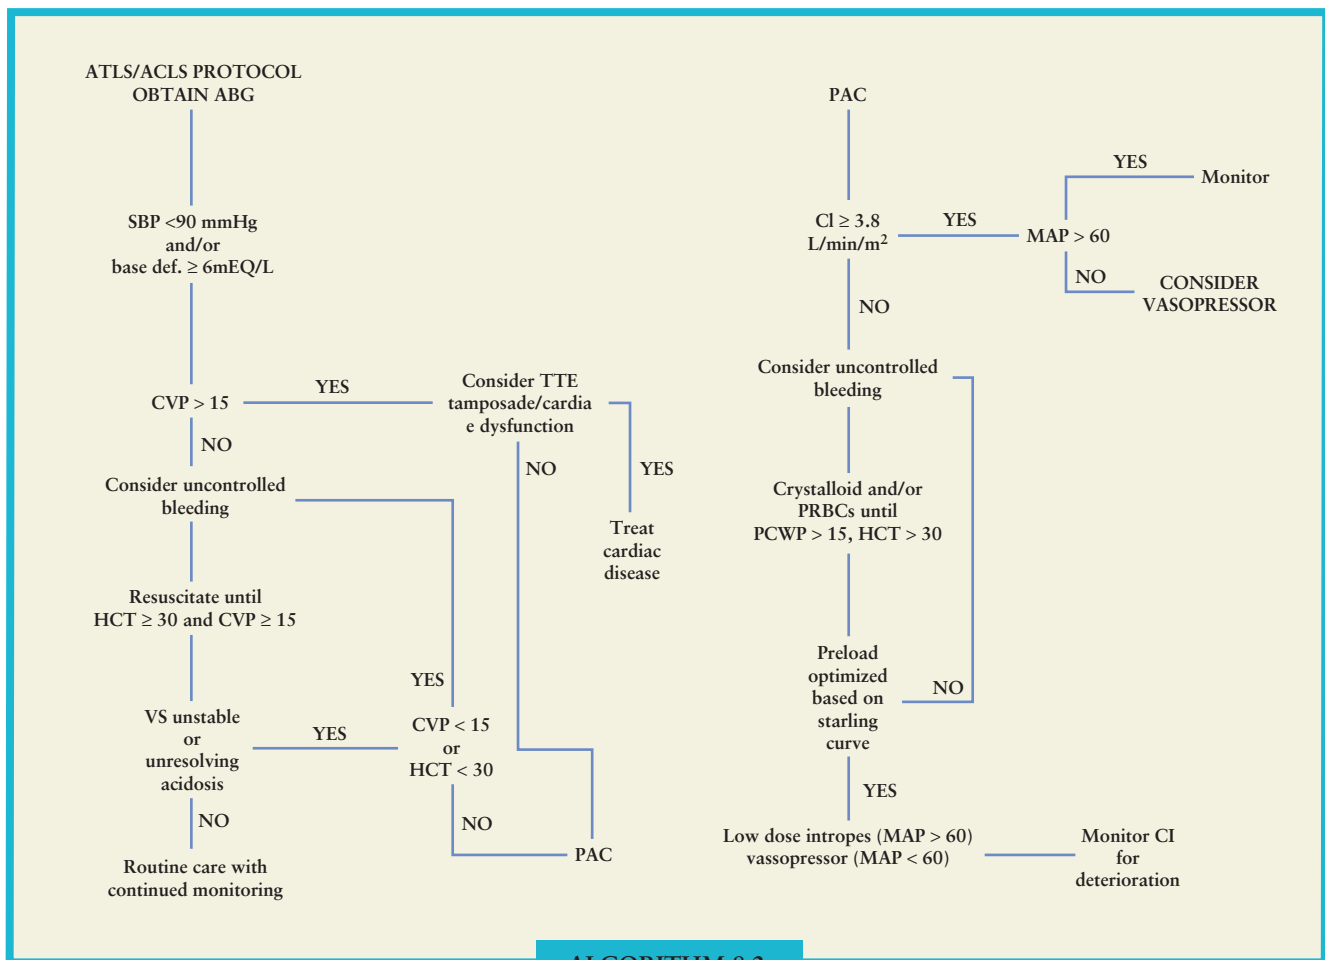

Neuroendocrine Response

The neuroendocrine reaction to shock consists of involuntary responses by the hypothalamus, autonomic nervous system, and secretory endocrine glands and is directed toward restoration of tissue perfusion and a redirected utilization of metabolic substrates. The autonomic response is initially triggered by hypoxia, hypotension, or hypovolemia detected by aortic and carotid baroreceptors and chemoreceptors (Algorithm 8.2). Subsequently, sympathetic vasoconstriction of specific vascular beds, induced by direct synaptic release of norepinephrine, results in redistribution of circulating blood volume from tissue of low metabolic activity to more metabolically demanding organs. Cardiac output, diminished by loss of preload, is

augmented by inhibition of cardiac vagal activity and a resulting reflex tachycardia.

Circulating epinephrine and norepinephrine alter several aspects of glucose utilization, availability, and metabolism. The hyperglycemia of stress results from catecholamine-induced glycogenolysis, gluconeogenesis, and decreased pancreatic insulin release. Simultaneously, hypothalamic stimulation of the anterior pituitary induces release of ACTH, which in turn prompts cortisol and aldosterone release by the adrenal cortex. Elevated serum cortisol contributes to postinjury hyperglycemia by increasing gluconeogenesis, enhancing lipolysis, and diminishing peripheral utilization of glucose and amino acids. The pancreatic response is characterized by a decrease in insulin release and an increase in glucagon secretion, which further stimulates hepatic gluconeogenesis. The combined actions of catecholamines, cortisol, and glucagon are synergistic and create a shock-related hyperglycemia that is often refractory to insulin treatment.

Renal juxtaglomerular secretion of renin in response to adrenergic stimulation and renal hypoperfusion triggers the formation of angiotensin I in the liver, which is subsequently converted to angiotensin II by the lungs. Angiotensin II, a potent vasoconstrictor, augments shock-induced catecholamine-mediated peripheral and splanchnic vasoconstriction and stimulates aldosterone release from the adrenal cortex. Renal tubular reabsorption of sodium in response to elevated circulating aldosterone creates highly concentrated, low-volume urine. Vasopressin secretion by the posterior pituitary similarly contributes to compensatory restoration and maintenance of intravascular

ALGORITHM 8.2

ALGORITHM 8.2. Shock resuscitation algorithm.

volume by promoting water reabsorption by the renal distal tubules and by causing peripheral and splanchnic vasoconstriction. A major result is a prolonged severe hypoperfusion of the splanchnic vascular bed, further augmenting the deleterious host response.

Immunoinflammatory Response

Many shock-inducing events, particularly those associated with septic or traumatic shock, simultaneously trigger a massive systemic inflammatory response. Although inflammatory mediators (TNF- α , ILs, chemokines, etc.) play an integral role in the recovery of local tissue to trauma and infection, an uncontrolled systemic inflammatory response contributes to organ failure. Immunologically active cells involved in the systemic inflammatory response include nucleated blood cells (monocytes, polymorphonuclear leukocytes [PMNs]) and platelets, microvascular endothelial cells, and tissue macrophages. These cells generate and secrete scores of signal-amplifying inflammatory mediators ranging in complexity from individual molecules (nitric oxide) to large multisubunit, extensively modified proteins (TNF- α , IL-1, etc.). Even transient systemic elevation of any of these mediators has profound physiologic consequences.

Local tissue destruction, microbial contamination, and infection similarly activate the coagulation cascade and induce platelet aggregation and release of numerous platelet-, endothelial-, and clot-derived vasoactive mediators. Persistent, profound, and recurring microvascular hypoperfusion of the splanchnic and other organs likewise causes local tissue ischemia, parenchymal cell injury, microvascular coagulation, activation of inflammatory cells, and release of inflammatory mediators. Circulating monocyte, lymphocyte, and PMN adherence to activated endothelium results in extraluminal transmigration of these inflammatory cells into tissues remote from the area of injury. This hyperdynamic immunologic response, with continued generation of proinflammatory mediators, is responsible for the progression of SIRS toward MODS.⁴²⁻⁴⁵

Regulation of the systemic inflammatory response has been an active area of shock research for several decades. Elimination of particular inflammatory mediators from the systemic circulation, or inhibition of particular cell-cell interactions in experimental animal systems, has been shown to improve outcomes after shock resuscitation.⁴⁶⁻⁴⁸ However, to date, all efforts to regulate the SIRS response with therapeutic elimination or supplementation of specific proinflammatory and anti-inflammatory mediators have proven ineffective or even harmful in humans. This lack of efficacy may relate to inadequacy of current animal models of shock, sepsis, and organ failure or to inadequate understanding of the full spectrum and interactive nature of key elements that regulate this syndrome. Unfortunately, the network of inflammatory mediators and affected cells is so complex and redundant that no single agent is likely to be effective at interrupting this response. As a result, there is probably no single common pathway likely to respond to a “silver bullet” approach.

Pulmonary Response

The lung is the organ system most sensitive to systemic insult and injury and is frequently the first organ to fail in the progression to MODS. ARDS represents a high-mortality form of pulmonary insufficiency that is often precipitated by sepsis or traumatic shock. It is triggered and perpetuated by the numerous inflammatory mediators created in the hypoperfused microvasculature elsewhere in the body.⁴⁹⁻⁵¹

Interstitial edema and subsequent reduced compliance result in diminished tidal volume and tachypnea, compromising gas exchange. Surfactant abnormalities contribute to alveolar collapse, resulting in loss of functional residual capacity

(FRC) and the onset of pulmonary insufficiency. The pulmonary microvascular response mirrors the systemic response, with angiotensin and α -adrenergic-induced vasoconstriction creating significant elevations of pulmonary vascular resistance, further straining the heart. Pulmonary parenchymal injury may be propagated by excessive positive-pressure ventilation generated by alveolar overdistention in particular, further contributing to alveolar damage.

No specific measures are available to reverse the ARDS process; therefore, aggressive management of predisposing conditions is most appropriate. Once ARDS has become fully developed, treatment involves intensive supportive care while minimizing iatrogenic insults. As a result, early utilization of lung-protective strategies may diminish progressive ventilator-induced lung injury and improve outcome.⁵²

Renal Response

Direct sympathetic-induced renal vasoconstriction increases afferent arteriole resistance in response to shock. This effect is reinforced by elevated circulating angiotensin II and catecholamines. The resulting decrease in renal blood flow and glomerular filtration rate (GFR), along with elevated circulating aldosterone and vasopressin (ADH), produce oliguria and prerenal azotemia. Acute tubular necrosis (ATN) may result from prolonged decreases in renal cortical blood flow, as well as from toxins generated during sepsis. Oliguric renal failure, like the pulmonary insufficiency of ARDS, is a common component of MODS.

Distinguishing low urine output due to oliguric renal failure from the oliguria of decreased renal perfusion pressure can be aided by analyzing urine sodium and osmolality. Renal hypoperfusion usually results in urine sodium of less than 20 mEq/L with an osmolality of greater than 400 mOsm/kg, whereas acute tubular injury impairs sodium reabsorption and is associated with a low urinary osmolality. A fractional excretion of sodium of less than 2% may also help determine whether the cause is renal or prerenal.

Early detection of abnormal kidney function is critical to prevent progression to renal injury. Abnormal renal function can be detected as a decline in creatinine clearance. The correlation between a creatinine clearance based on a 24-hour collection and a sample collected over a shorter interval is poor. However, the 24-hour value represents an average value over that time. A sample obtained over a shorter period may reflect the time in question and allow timely recognition and treatment of renal dysfunction.

Hepatic Response

Ischemic injury to liver is not apparent early during shock. However, the liver plays an important role in the regulation of shock and subsequent tissue injury through both the release of acute-phase reactants and lack of clearance of potential toxic agents. As shock continues, hepatic necrosis occurs, leading to the release of aspartate aminotransferase and alanine aminotransferase. Continued shock results in attenuated synthesis of coagulation factors, albumin and prealbumin. Although progressive ischemia can occur, leading to complete loss of glycogen stores and marked hypoglycemia, this condition is rare without preexisting liver disease, significant direct liver injury, or hepatic artery occlusion.

Genetic Regulation of the Response to Shock

Individuals vary considerably in their susceptibility to shock and in their ability to recover from its consequences. Recently,

unique host-specific responses have been identified as important determinants of the outcome of sepsis and septic shock. Genetic predispositions in an individual's immunoinflammatory response may dictate whether infection is adequately or inadequately countered. These differences in response may be partially explained by single nucleotide polymorphisms (SNPs) in the genetic sequences for various inflammatory mediators. These subtle nucleotide variations may affect the transcription or translation of associated genes or the secretion or function of the corresponding proteins.

The recognition that genetic background may regulate the response to severe sepsis and septic shock has led to the identification of an array of genetic markers associated with enhanced risk of septic mortality. These SNPs are in genes encoding proteins involved in pathogen recognition (toll-like receptors 2, 4, and 5; CD14; and mannose-binding lectin), cytokine expression (TNF- α , IL-1, IL-6, and IL-10), and several other genes involved in mediating and controlling the innate immune response and the inflammatory cascade.^{53,54}

Investigation into genetic polymorphisms should provide important insights into the pathophysiology of shock. SNP identification leading to early diagnosis of individuals at risk of developing or dying from the complications of shock may allow therapies to become more preemptive and effectively targeted.

LOSS OF COMPENSATORY RESPONSES TO SHOCK

If shock is prolonged, the arteriolar and precapillary sphincters become refractory and relax, while the postcapillary sphincter remains in spasm. Therefore, the capillary hydrostatic pressure increases, and Na⁺, Cl⁻, and water are moved into the interstitium, leading to depletion of intravascular volume.

Cellular membrane function is also impaired with prolonged shock. The normal negative membrane potential approaches neutrality, leading to increased permeability and interstitial flooding by K⁺. This is caused, at least in part, by a decrease in the normal function of the adenosine triphosphate-dependent Na⁺-K⁺ membrane pump that is a result of cellular hypoxia. The loss of the membrane potential difference leads to cellular swelling due to an intracellular influx of Na⁺ and fluid.

In addition to these cellular effects, severe and prolonged shock results in the development of progressive organ dysfunction. Although the mechanisms responsible are incompletely understood, it appears that the vital organs, in particular the lung early on, are limited in their ability to protect themselves during shock. As a result, direct endothelial injury occurs, resulting in leakage of various inflammatory mediators, which in turn results in accumulation of interstitial fluid and subsequent reduction in nutrient and gaseous diffusion. This condition, along with progressive microcirculatory thrombosis, is responsible for the late organ dysfunction characteristic of uncompensated shock.

COMPLICATIONS OF SHOCK

Ischemia-Reperfusion Injury

- 6 Inadequate microvasculature flow results in activation of leukocytes and converts local endothelial cells to a proinflammatory, prothrombotic phenotype. On reperfusion, the reintroduction of oxygen prompts these cells to generate superoxide anion, hydroxyl radicals, and hydrogen peroxide, further injuring local tissue. Microvascular endothelial adherence, monolayer transmigration, and local oxidative burst by activated neutrophils, along with the profound loss of endothelial monolayer integrity (i.e., microvascular capillary leak), contribute to

massive interstitial edema after reperfusion. Although all tissues are sensitive to varying degrees, ischemia-reperfusion injury appears to be most detrimental to the pulmonary vasculature and the splanchnic circulations. Pulmonary interstitial edema and alveolar fluid accumulation are associated with the development of ARDS, whereas extensive visceral edema may contribute to development of abdominal compartment syndrome and mesenteric ischemia.

Second-hit Phenomena

Patients who have been successfully resuscitated from shock are at risk for what is referred to as the second-hit phenomenon. A single episode of severe or prolonged shock may precipitate organ failure, but, in addition, the initial insult may "prime" the inflammatory response, resulting in an augmented or prolonged response to a subsequent insult such as an infection, a second episode of blood loss, or major surgery.⁵⁵ For example, after the primary event, circulating neutrophils demonstrate enhanced superoxide anion production, increased endothelial cell adherence, augmented cytokine response, and increased cytotoxicity. Not only do circulating innate immune cells demonstrate this priming effect, but tissue-fixed cells, in particular the macrophage, demonstrate altered phagocytosis and augmented cytokine release.⁵⁶ This dysfunctional response leads to not only diminished microbial clearance and enhanced risk of nosocomial infection but also increased host tissue injury and subsequent development of MODS.

Multiple Organ Dysfunction Syndrome

Multiple organ dysfunction syndrome rarely develops as a result of isolated cardiogenic or neurogenic shock but is most often precipitated by septic and traumatic shock complicated by second-hit events such as repeated episodes of hypovolemia, subsequent infection, or repeated blood transfusions. Similarly, the presence of an unresolved inflammatory focus (such as devitalized necrotic tissue), undrained bodily fluids, or unresolved regional perfusion deficits can be the primary causes for the persistence of SIRS and the transition to MODS.

The effects of shock, resuscitation, and reperfusion and the subsequent development of MODS appear to depend on changes in the splanchnic and pulmonary microcirculations. These vascular beds appear to be major sites of the activation and subsequent immunoinflammatory mediator production that is responsible for the SIRS response. As splanchnic microcirculatory flow decreases in response to homeostatic vasoconstrictive responses during hypovolemia, excessive and prolonged hypoperfusion of the gut results in extensive microvascular injury and subsequent activation of endothelium, neutrophils, and macrophages. In addition, mucosal barrier disruption permits translocation of bacteria and bacterial toxins to circulate and reach the large tissue-fixed macrophage population in the liver. Extensive activation of the Kupffer cells in the liver results in the release of inflammatory mediators that cause distant organ injury through the systemic activation of other immune cells.

Not only is a proinflammatory phase of SIRS present, but there is also a compensatory anti-inflammatory phase of the SIRS response that is evolutionarily designed to counter the locally generated hyperimmune response and check systemic spread of proinflammatory mediators. If the compensatory anti-inflammatory response syndrome (CARS) results in excessive immunosuppression, it may contribute to susceptibility to primary and secondary infections that can then lead to organ failure.⁵⁷

Numerous clinical trials utilizing proinflammatory and anti-inflammatory mediators as therapeutic interventions have been conducted. Unfortunately, few therapeutic agents designed to

counter immune dysfunction have had significant impact on the prevention and treatment of MODS. In fact, with the exception of activated protein C, all attempts have failed to sufficiently and appropriately stimulate or suppress the SIRS response and improve outcomes.⁵⁸

Abdominal Compartment Syndrome

Abdominal compartment syndrome is a highly morbid complication of reperfusion injury to the splanchnic viscera. This syndrome appears to be increasingly prominent due to aggressive resuscitation techniques that enable salvage of profoundly hypotensive and hypovolemic patients. Splanchnic ischemia and reperfusion result in extensive visceral capillary leak and interstitial edema of the bowel. Excessive volume resuscitation during this phase leads to grossly edematous viscera within the closed space of the abdomen, which dramatically increases intra-abdominal pressure, and compromises intra-abdominal organ function, increases renovascular resistance, limits diaphragmatic excursion, and may decrease cardiac output and elevate intracranial pressure. The clinical hallmarks of abdominal compartment syndrome are a distended and tense abdomen, diminished tidal volume, pulmonary edema, decreased cardiac output, oliguria, and elevated urinary bladder pressure. Presence of all or a major part of this syndrome should prompt consideration of an urgent operative laparotomy to decompress the abdomen and treat by leaving the abdomen open.

Hypothermia

Hypothermia (core temperature $<35^{\circ}\text{C}$) is common during shock. In addition to immobilization, both prehospital and postadmission exposure can lead to conductive, convective, and evaporative heat loss, which should all be minimized. In addition, the administration of room temperature intravenous fluids and of cold-stored blood also contributes to hypothermia.⁵⁹ Hypothermia increases fluid requirements and independently increases acute mortality rates.⁶⁰

As the core temperature decreases, the rate of oxygen consumption also decreases, to approximately 50% of normal at 28°C . The decrease in oxygen consumption is accompanied by increased production of acid metabolites. A leftward shift in the oxyhemoglobin dissociation curve also occurs with hypothermia but is partially compensated by the acidosis. Central nervous system effects progress from confusion and loss of manual dexterity to obtundation and frank coma as the core temperature decreases from 35°C to 26.5°C . The heart rate decreases to approximately half of baseline at 28°C , with a concomitant decrease in cardiac output. All cardiac electrical conduction intervals are prolonged, consistent with the changes in heart rate, and both atrioventricular dissociation and refractory ventricular fibrillation occur at 28°C . Other potential physiologic effects include ileus and pancreatitis (from cold enzyme activation) at temperatures lower than 35°C .

Compensatory responses to hypothermia include increased excretion of catecholamines, resulting in doubling of the basal metabolic rate, and increased production of thyroid hormones, further increasing the basal metabolic rate to five times baseline. Shivering can increase heat production as well, but it represents a significant energy expenditure, and has been shown to be inhibited during episodes of hypotension or hypoxemia.⁶¹ Compensatory responses to hypothermia are lost at temperatures below 30°C or 31°C , and a state of complete poikilothermy is reached.

The treatment for hypothermia is rewarming. The core temperature should be obtained on admission of the trauma patient. Patients whose core temperatures are 33°C to 35°C can be treated with passive rewarming, warm blankets, and hot

packs. Patients with core temperatures lower than 33°C require active rewarming. If the patient is unconscious, airway control should first be obtained. Because severe hypothermia causes vasoconstriction, noninvasive blood pressure measurements may not be feasible or accurate, and an arterial line should be placed for monitoring and blood gas sampling. The inspired gas through the ventilator should be heated to 41°C and fully saturated with water vapor to increase heat conductance in the lung. The intravenous fluids should also be warmed. Commercially available rapid infusion systems with countercurrent heating elements should be used. For extreme hypothermia, continuous mechanical arteriovenous rewarming can be performed for both circulatory support and rewarming. Recently developed microtechnology permits core rewarming by percutaneous placement of countercurrent warming coils directly in the inferior vena cava. Finally, other warming methods include lavage of heated saline through nasogastric and thoracostomy tubes as well as peritoneal lavage, but are not as effective.

Coagulopathy

Coagulopathy is a frequent problem complicating shock, especially in those patients who have received large volumes of crystalloid solution and blood for resuscitation. Although this problem is incompletely understood, it is clear that coagulation defects during shock are multifactorial. The presence of shock, the fluid volume required for resuscitation, the presence of hypothermia, and preexisting diseases all influence the likelihood and severity of coagulopathy.⁶²

A major factor in coagulopathy is usually due to the dilutional thrombocytopenia that occurs after massive volume resuscitation. Although bleeding times can be prolonged with platelet counts less than 100,000 cells/mL, platelet counts of 50,000 cells/mL or greater are usually adequate for surgical hemostasis. Dilutional thrombocytopenia becomes more likely with infusions of more than one blood volume. Each unit of platelets administered increases the platelet count by 10,000 to 15,000 cells/mL. Control of surgically remediable hemorrhage is prudent before platelet transfusion to prevent the loss of the transfused platelets.

Dilution of other coagulation factors also plays a role in development of coagulopathy. Factors V and VIII are the most labile in banked blood, but levels of less than 10% of normal for factors VII, X, XI, XII, and XIII are all associated with abnormalities in hemostasis, as demonstrated by prolonged partial thromboplastin time and prothrombin time. Fresh frozen plasma can be administered as a source of all the soluble coagulation factors. The administration of cryoprecipitate may be necessary as a concentrated source of factor VIII and fibrinogen, particularly if adequate hemostasis is not obtained with the use of fresh frozen plasma.

Recent support has emerged for the use of recombinant activated factor VIIa. Although developed initially for use in hemophiliacs who developed inhibitors to factor VIII, anecdotal evidence has suggested that recombinant activated factor VIIa may serve to quickly reverse hemorrhage-induced coagulopathy.⁶³ However, currently no definitive data exist on which patients may benefit, and therefore further studies are required before routine use can be advocated.

Finally, evidence has suggested that coagulopathy and hemorrhage can be minimized following massive blood loss if early aggressive use of fresh frozen plasma is administered. Military data demonstrate that significant early coagulopathy is present after massive injury, even before blood component therapy is begun. Both civilian and military experience with a 1:1 ratio of packed red blood cells to fresh frozen plasma has been associated with reduced mortality.^{64–66} However, this practice has been associated with an increase in the development of ARDS and organ dysfunction due to poorly defined mechanisms.⁶⁷ Thus, generalization of this data to all patients with hemorrhage

other than the massively injured should be performed with caution until further prospective evidence is available.

TREATMENT

Fluid Therapy

Early investigators of hemorrhagic shock noted that decreased CVP and a reduction in total body oxygen delivery (DO_2) were key early findings. If the decrease in oxygen delivery was severe or prolonged, a reduction in total body oxygen consumption ensued. After adequate fluid resuscitation, oxygen delivery and consumption increased above the baseline value for several hours, as if the body was paying back an “oxygen debt.” Failure of the patient to achieve this hyperdynamic response to resuscitation was almost always fatal. Because early death from shock appeared to be explained by the dynamics of oxygen delivery and utilization, therapy focused on restoring hemodynamics and oxygen transport with fluid and inotropes.

The provision of additional fluid beyond the amount of blood loss was associated with improved survival in both clinical and experimental studies of hemorrhagic shock, leading to widespread acceptance of aggressive fluid infusion. However, some researchers have recently described a significant increase in mortality associated with crystalloid overresuscitation and have postulated that excessive fluid administration increases the clinical risk of ARDS, MODS, increased intracranial pressure, and abdominal compartment syndrome.^{68–70} Because massive volumes of fluid are only provided to patients with severe shock, it is unclear if it is the excessive fluid or the associated underlying shock that increases the risk of ARDS, organ failure, or death after massive fluid resuscitation.

- 7 A minimum of two large-bore (14- to 16-gauge) intravenous catheters should be established in adults. Isotonic fluid is then infused at the same time as blood is obtained for arterial blood gas analysis, screening, and typing. Fluid can be infused up to 200 mL/min through a 14-gauge catheter and up to 220 mL/min through a 7-French catheter. A fluid challenge of 10 to 25 mL/kg is administered to the hypotensive patient and the response is assessed (i.e., 2,000 mL or 40% of blood volume of a 70-kg man). This therapeutic challenge is an effective trial in determining the amount of preexisting or continuing volume loss. If the blood pressure returns to normal and is stabilized, the volume loss was relatively small, and the only treatment required may be infusion of isotonic fluid.

If the increase in blood pressure is transient after fluid bolus, then hemorrhage or continued fluid losses are severe and ongoing. Additional crystalloid is administered, and the need for blood transfusion is assessed. Patients who continue to require large amounts of fluid and blood to support perfusion usually have ongoing hemorrhage and require surgical intervention. No response or a minimal response to apparently adequate infusions of crystalloid solution and blood indicates exsanguinating hemorrhage and the need for urgent surgery.

Crystalloids. Balanced salt solutions are the most commonly used resuscitative fluids, and their use to restore extracellular volume significantly decreases the transfusion requirement after hemorrhagic shock. Lactated Ringer solution is isotonic, readily available, and inexpensive. It rapidly replaces the depleted interstitial fluid compartment and does not aggravate any preexisting electrolyte abnormalities. Previous investigations have shown that administration of lactated Ringer solution does not lead to aggravation of the lactic acidosis that is present in shock.⁷¹ In fact, animal models have demonstrated that the use of blood plus lactated Ringer solution results in a more rapid return to normal lactate and pH than dose shed blood alone. As volume and perfusion are restored, lactate is mobilized and metabolized to bicarbonate in a single

pass through the liver. In fact, mild metabolic alkalosis may occur 1 or 2 days after large-volume resuscitations with lactated Ringer solution. Normal saline solution is also effective for resuscitation of hypovolemic patients. Concerns about inducing hypernatremic, hyperchloremic metabolic acidosis with massive resuscitation volumes remain but appear of less relevance by further investigation with normal saline and the hypertonic saline solutions.

Recently several investigations have raised concerns about the proinflammatory effects of resuscitation with lactated Ringer solution. Some commercially available lactated Ringer solutions contain racemic lactate that is made of equal concentrations of D(–) and L(+)-isomers of lactate. The D(–)-isomer has been demonstrated in vitro to result in enhanced production of reactive oxygen species by neutrophils and inflammatory gene expression by leukocytes.^{72,73} In addition, increased apoptosis in both the small intestine and the liver was seen after resuscitation from hemorrhage with lactated Ringer solution, but not with hypertonic solutions or blood resuscitation.⁷⁴ These findings, however, are not consistent and do not appear dissimilar from saline resuscitation in other animal models.⁷⁵ Thus, further investigations are required to determine the overall inflammatory effect of crystalloid resuscitation and extent of D(–)-isomer use in current commercial fluids.

Colloids. Colloids have the theoretic advantages of increasing the colloid oncotic pressure and requiring smaller volumes for resuscitation than crystalloids.⁷⁶ Colloids commonly used for volume expansion in hypovolemia include albumin, dextran 70, dextran 40, and hydroxyethyl starch. Although each has unique individual characteristics, currently there is little justification for the routine addition of colloids to balanced salt solutions for volume replacement during shock.

Albumin solutions have been used during resuscitation to increase colloid oncotic pressure and, hypothetically, to protect the lung from interstitial edema; however, there is a relatively rapid flux of albumin across the pulmonary capillary membranes and relatively rapid clearance through the pulmonary lymphatics. In fact, colloid albumin infusion has been demonstrated to prolong the resuscitation phase and delay postresuscitation diuresis. Additionally, albumin may serve to depress circulating immunoglobulin levels and suppress albumin synthesis.

Dextran 40 and dextran 70 are polysaccharides with molecular weights of 40 and 70 kD, respectively. Dextran 40 (10%) is hyperoncotic and initially exerts a volume-expanding effect. However, because of its lower molecular weight, it is more rapidly excreted. Thus, dextran 40 is commonly used in cases of peripheral vascular disease and hyperviscosity syndromes. Dextran 70, conversely, is provided as a 6% solution and does not exert a hyperoncotic effect. The volume expansion is somewhat greater than the amount infused, and because of its large molecular size the effect is maintained for up to 48 hours. The dextran preparations, however, cause decreased platelet adhesiveness and decreased factor VIII activity. They also carry an incidence of allergic reaction of up to 5% and anaphylaxis of 0.6%.⁷⁶

Hydroxyethyl starch is an amylopectin with volume-expanding effects for approximately 36 hours. It has side effects similar to those of dextran, but with less frequency. The incidence of anaphylaxis is 0.006%. A new hydroxyethyl starch, pentastarch, has a lower molecular weight and fewer hydroxyethyl groups than hydroxyethyl starch. Pentastarch has a shorter duration of action (2.5 hours) and has been reported to have even fewer side effects.^{77,78}

The controversy regarding use of crystalloids versus colloids in resuscitation has not been resolved. Both types of solutions can restore circulating volume. The effects of the solutions on pulmonary function are at issue and are summarized as follows: (a) the use of crystalloid solutions decreases plasma oncotic pressure, thereby leading to lung edema at lower

microvascular pressures; and (b) colloids given in the face of pulmonary injury can extravasate, promoting edema because of the reduced plasma interstitial oncotic gradient. In fact, a previous meta-analysis of colloid versus crystalloid resuscitation after hemorrhagic shock demonstrated a higher mortality rate among the colloid-resuscitated patients, partly because of pulmonary complications.⁷⁹ Therefore, since colloid infusion has not demonstrated a significant benefit over crystalloid resuscitation alone, it is not currently recommended in the management of hypovolemic shock.

Resuscitative Strategy. Aggressive fluid resuscitation is clearly a lifesaving modality, and a key strategy in the treatment of shock and prevention of secondary consequences (Algorithm 8.2). However, indiscriminate fluid loading causes problematic edema in the lungs, gut, brain, and other organs. The amount of fluid used for resuscitation should be titrated to carefully selected hemodynamic and oxygen transport endpoints. Solutions currently in development (“artificial blood”) with oxygen transport capabilities may hold the potential of restoring oxygen transport while minimizing the need for large volumes.

Permissive Hypotension

Elevation of systemic arterial pressure in patients with disruption of the arterial system or major solid organ injury, especially after penetrating trauma, may cause acceleration of hemorrhage, disrupt natural clotting mechanisms, and cause dilution of clotting factors. Laboratory and clinical evidence support judicious use of intravenous fluids until hemorrhage is controlled by surgery, angiography, or direct pressure for penetrating trauma.⁸⁰ Fluid resuscitation for patients with multi-system blunt trauma, especially with concomitant traumatic brain injury, represents a more complicated decision process, as maintaining cerebral perfusion pressure is a competing priority. Avoidance of both excessive fluid administration and prolonged hypoperfusion is best achieved in all patients not by maintenance of a marginal blood pressure, but by rapid surgical or angiographic intervention to control bleeding.

Transfusion

Anemia prompts clinical concerns because it may signify blood loss or hematologic disease, but it rarely causes tissue ischemia. The hemoglobin level that causes concern should depend on the adequacy of other mechanisms involved in oxygen delivery such as arterial oxygen saturation and cardiac output, the specific clinical situation, and the organ systems most at risk, balanced against the risk of transfusion. Clinical evidence suggests that hemoglobin values above 7 mg/dL are adequate in most patients, including the critically ill, but this has not been explored during shock. In one prospective randomized trial in critically ill patients, it was clearly demon-

strated that a reduction in complications and improvement in survival were noted when lower hemoglobin values were accepted.⁸¹ However, this study excluded patients with hypovolemia, acute coronary syndrome, and sepsis. Thus, the role of transfusion during shock remains problematic.

Given this limitation, currently it is held that most patients with class I or II shock can be resuscitated with balanced salt solutions alone. Patients who lose more than 25% to 30% of total blood volume require blood for resuscitation, as do patients with persistent evidence of inadequate end-organ perfusion.¹⁶ The decision about the extent of blood cross match prior to being transfused is determined in part by the urgency of the situation. Blood that has been fully typed and cross matched carries the least risk of transfusion reactions, but it also takes the most time to obtain. Other transfusion options include the use of type O or type-specific blood (Table 8.6).

Type O Blood. Type O (universal donor) blood is immediately available without a cross match. Because type O blood contains no AB cellular antigens, administration of packed red blood cells is relatively safe in patients of any blood type. Males should be transfused type O Rh-positive blood, while prepubescent females and females of childbearing age should be given type O Rh-negative blood to avoid sensitization that would complicate future pregnancies. The administration of more than 4 units of type O blood to a non-O-blood-type patient, however, theoretically can result in an admixture of blood type. A pretransfusion blood specimen should be sent to the blood bank when the patient is admitted, and type-specific blood should be transfused as soon as it is available.

Type-specific Blood. Type-specific blood is available from most blood banks within 5 to 10 minutes of receipt of the blood specimen, while the patient is being resuscitated with balanced salt solutions. Although not cross matched, this blood can be administered safely, as demonstrated in both military and civilian experiences.⁸²

Autotransfusion. Autotransfusion involves collection of the shed blood and its reinfusion through a filter back into the patient. Autotransfusion can be as simple as aspiration of the blood into a citrate-containing collection chamber, followed by reinfusion through a 40-mm filter. A more elaborate system, the Haemonetics autotransfuser (Haemonetics Corp., Braintree, MA), centrifuges the collected blood and delivers washed, packed red blood cells for reinfusion. The advantages of autotransfusion include transfusion with warm, compatible blood without delays and with no risk of transmission of hepatitis, human immunodeficiency virus, or other blood-borne pathogens.

Autotransfused blood can produce disseminated intravascular coagulation and activation of fibrinolysis. In addition, collection of blood from the peritoneal cavity after hollow viscus injury, even with cell washing, may lead to bacterial contamination of the autotransfused blood.⁸³ Successful autotransfusion of contaminated blood has been demonstrated, but blood

TABLE 8.6

COMPARISON OF BLOOD AVAILABILITY

■ BLOOD	■ TYPING	■ ANTIBODY SCREEN	■ CROSS MATCH	■ TIME
Type O	No	No	No	Immediate
Type specific	Yes	No	No	<10 min
Type and screen	Yes	Yes	Yes	20–30 min
Type and cross match	Yes	Yes	Yes	45–60 min

obtained from enteric-contaminated cavities probably should not be used, except perhaps in extreme circumstances.⁸⁴ Despite the potential benefits, investigators have found that the autotransfuser was used in only 26% of the trauma patients for whom it was prepared.⁸⁵ Currently, no evidence exists that autotransfusion improves outcome compared to exclusive homologous blood transfusions in trauma patients.

Endpoints of Resuscitation

Endpoints of resuscitation can be categorized as either global or regional indicators of perfusion. Blood pressure and pulse are global measures and are relatively poor determinants of the adequacy of tissue oxygenation. They must also be interpreted in the context of patient age and preexisting medical conditions. Tachycardia is a component of SIRS and does not always resolve with increased preload. Arterial pressure is maintained by myriad compensatory mechanisms, even in the face of a significant volume deficit, and interpretation is complicated by highly variable baseline pressures, age, and preexisting medical conditions.

Base deficit and serum lactate are also global indicators of perfusion and may help in the detection of patients who are in otherwise compensated shock. Acidosis arising from regional tissues may not be apparent in peripheral blood samples, as is frequently the case in patients with intestinal ischemia, in whom systemic acidosis is a late finding. An elevated base deficit and lactate can be caused by electrolyte abnormalities, accelerated glycolysis or pyruvate production, and/or decreased clearance by the liver. They may also reflect dysfunction caused by a period of hypoperfusion that has already resolved and that does not need further treatment. A positive response toward correction, however, is indicative of appropriate resuscitation.

A pulmonary artery catheter (PAC) has obvious appeal as a monitor because ensuring adequate oxygen delivery is paramount in the treatment of shock (Algorithm 8.2). A progressive decline in systemic oxygen delivery (DO_2) results in an increase in the oxygen extraction ratio, evident as a reduction in pulmonary mixed venous oxygen saturation. When DO_2 is reduced below the level needed to maintain normal tissue metabolic activity, anaerobic metabolism occurs. This is evident as a decrease in total body oxygen consumption (VO_2). Adequate resuscitation requires eliminating any pathologic decrease in VO_2 by restoring oxygen delivery to an adequate level. In clinical practice, however, there is no precise level of VO_2 that can be used as an endpoint, as tissue oxygen needs vary according to the patient's condition, level of sedation, body temperature, and other factors, and are affected by endogenous and exogenously administered catecholamines.

Oxygen consumption may be especially difficult to interpret in patients with late-stage sepsis because acquired defects in mitochondrial respiration may prevent utilization of oxygen, resulting in decreased consumption and progressive acidosis despite normal or high DO_2 .

The adequacy of resuscitation can also be assessed by measurement of end-organ function and perfusion, in addition to global measures. Blood flow to the most vital organs (brain and heart) is preserved during shock at the expense of flow to the skin, muscles, gut, and, ultimately, kidneys. Detection of ischemia in less vital organs could theoretically identify patients in compensated shock who have otherwise normal global indicators.

Low urine output (<0.5 to 1.0 mL/kg per hour) is an indicator of inadequate end-organ perfusion, but inappropriate urine output may initially be maintained by peripheral vasoconstriction and maintenance of cardiac output due to tachycardia. The use of gastric tonometry to measure intramucosal pH has highlighted the uneven recovery from shock by visceral organs. Persistent visceral hypoperfusion, as demonstrated by intramucosal acidosis despite correction to normal hemodynamics, is

associated with organ failure and poor outcomes. Unfortunately, direct measurement of visceral hypoperfusion, as well as hypoperfusion in other regional vascular beds, requires use of technically challenging, labor-intensive devices that often produce variable unreliable results and has not yet had widespread application. Presently, the goal of therapy is to restore tissue perfusion, both global and regional as measured by organ function, and to normalize cellular metabolism while avoiding excessive use of fluids and inotropes.

Recently, several biomarkers, in addition to base deficit and lactate, have demonstrated potential promise. Among the most promising is procalcitonin for the early recognition of sepsis. However, in addition to being significantly elevated during sepsis, procalcitonin has recently been demonstrated, similar to lactate and base deficit, to be prognostic of outcome from hypovolemia based on rate of clearance.⁸⁶ Thus, this biomarker along with potential others may lead to early recognition and treatment of shock.

MONITORS

Central Venous Pressure

CVP is determined by a number of factors, the most important of which are venous volume and venous compliance. Cardiac output and arterial dilation modulate CVP by affecting central venous volume, whereas sympathetic vasoconstriction and thoracic and intra-abdominal pressure primarily affect central venous compliance. A variety of conditions can raise CVP despite a normal or even low cardiac preload. High ventilator pressures, expiratory airway obstruction, tension pneumothorax, cardiac tamponade, and obesity are additional non-volume-dependent causes of a relatively elevated CVP.

Circulating catecholamines cause vasoconstriction, with maintenance of venous pressure despite reduced circulating volume. In such cases, fluid therapy may reduce the intensity of vasoconstriction by reducing tone, with no net change in CVP. Following the change in CVP in response to a fluid challenge may be the only way to accurately estimate preload in some patients. Although an elevated CVP does not guarantee adequate preload, a low CVP is a reliable indicator of hypovolemia. Inspiratory stridor is the only condition that can falsely reduce CVP and mimic hypovolemia by significantly reducing intrapleural pressure.

Pulmonary Artery Catheter

Hemodynamic monitoring utilizing a flow-directed PAC has been a standard in the treatment of shock for decades and has been considered to be essential for optimal management of certain forms of shock. However, as a result of a multicenter study that reported that use of a PAC was associated with increased mortality, the indications for PAC use have recently been questioned.⁸⁷ PAC patients were retrospectively compared to matched control patients that were selected using a scoring system. This scoring system has not been validated, which raises the possibility that physicians inserted a PAC in the more critically ill patients.

Intensive care unit (ICU) staffing practices may have also been a factor explaining these surprising results. The study was conducted in "open" ICUs, where any physician on the medical staff could admit a patient to the unit and insert a PAC. Clinicians may not always interpret PAC data appropriately. In a multicenter study of physicians' knowledge and interpretation of PAC data, nearly half (47%) were unable to appropriately determine the wedge pressure from a clear tracing, and a similar percentage (44%) could not identify the determinants of oxygen delivery.⁸⁸ Studies have demonstrated improved outcome when patients are managed in ICUs staffed

by specialists in critical care, despite their more frequent use of PACs.⁸⁹

An additional consideration regarding the controversy over the utility of PACs is that currently used endpoints for PAC-guided resuscitation may be inappropriate. For example, efforts to augment systemic oxygen delivery have not demonstrated any benefits and, in fact, harm may be caused this approach, whereas treatments used to alter the variables ascertained with the catheter may themselves cause harm (fluid overload, excessive inotropes, blood transfusions). Finally, PACs are associated with specific complications, including the risk of central venous catheter insertion, endocarditis, and pulmonary artery injury, which may outweigh any potential benefits. As the safety and utility of the PAC have not yet been evaluated with prospective clinical trials in specific shock states, its usefulness in the management of shock remains to be determined.

Newer versions of the PAC have been developed that provide additional hemodynamic information, including continuous determination of cardiac output, ejection fraction, and calculated right ventricular end-diastolic volume. The pulmonary artery wedge pressure is a proxy for preload. However, the amount of precontractile stretch achieved with any given wedge or chamber pressure is modulated by the compliance of the ventricle. Therefore, cardiac chamber pressure may not be an accurate indicator of ventricular end-diastolic volume, just as end-diastolic volume may not be an accurate indicator of pulmonary wedge pressure and/or risk of pulmonary edema. The combination of both wedge pressure and end-diastolic volume may be optimal to maximize preload while avoiding excessive pulmonary capillary pressure.

A comparison of the pH and partial pressure of carbon dioxide (PCO₂) of mixed venous blood with a matched arterial blood sample can provide evidence of shock with tissue hypoxia. Hypoxic cells generate a hydrogen ion that is buffered by bicarbonate, resulting in increased production of H₂O and CO₂. An increase in venous PCO₂ results in an abnormal gap between mixed venous and arterial PCO₂ and pH and is a sign of anaerobic metabolism. With cessation of hydrogen ion production, this abnormal gap is quickly eliminated, whereas base deficit and hyperlactatemia may persist for several hours.

PHARMACEUTICAL SUPPORT

Therapeutic adjustments of preload and afterload form the basis of treatment strategies in all forms of shock. Optimal volume resuscitation should always precede measures to augment the contractile function of the heart. Inotropic augmentation of cardiac output may therefore be required when restoration of venous preload fails to provide sufficient cardiac output to satisfy tissue oxygen demands. The effect of inotropic agents depends on the specific adrenergic receptor affinity, chronotropic effects, and demands placed on myocardial oxygen consumption of the individual agents (Table 8.7). Vasodilators reduce demands on the myocardium and augment cardiac function via reduction in systemic vascular resistance (SVR) or afterload or by dilating the venous system and reducing cardiac preload. Afterload reduction may preserve stroke volume in the face of a failing myocardium, whereas

α (alpha), vasoconstrict peripheral arterioles; β_1 (beta-1) myocardial inotropy, chronotropy, enhance atrioventricular conduction; β_2 (beta-2) chronotropy, vasodilate mesenteric/skeletal bed, bronchodilation; dopaminergic, vasodilate mesenteric/renal bed. BP, blood pressure; CO, cardiac output; SVR, systemic vascular resistance.

venodilation reduces pulmonary capillary wedge pressure and pressure-driven pulmonary edema. Agents that increase afterload may be needed when blood pressure falls below the autoregulatory range of the coronary, cerebral, and renal vascular beds.

Inotropes and Vasopressors

Dopamine. Dopamine is an endogenous sympathetic amine that is a biosynthetic precursor of epinephrine and functions as a central and peripheral neurotransmitter. The effects of dopamine vary from individual to individual, and are altered with increasing doses. The highest-affinity receptors are occupied at low serum concentrations (infusions <2 to $3 \mu\text{g/kg}$ per minute) and consist of dopaminergic receptors in the renal and splanchnic beds that serve to augment regional blood flow, increase urine output, and cause natriuresis. However, multiple studies, including prospective randomized trials, have failed to demonstrate that low-dose dopamine prevents acute renal failure or decreases the need for dialysis in critically ill patients. At modest concentrations (3 to $5 \mu\text{g/kg}$ per minute), dopamine occupies cardiac β_1 -adrenergic receptors and increases myocardial contractility and heart rate. Higher doses ($>5 \mu\text{g/kg}$ per minute) cause an increase in heart rate and blood pressure. α -Adrenergic receptors are stimulated at higher dose ranges ($>10 \mu\text{g/kg}$ per minute), resulting in elevation of blood pressure and peripheral vascular resistance. Dopamine is therefore an effective agent for increasing blood pressure in hypotensive patients after appropriate fluid resuscitation. Because the relationship among a specific dose, receptor affinity, and clinical effect is unique to each patient, individual titration is required to achieve the desired effect.

Dobutamine. Dobutamine, a synthetic catecholamine, has a predominant affinity for β -adrenergic receptors. At clinically relevant doses (5 to $20 \mu\text{g/kg}$ per minute), dobutamine enhances myocardial contractility with mild to moderate changes in heart rate. It also induces peripheral vasodilation, which limits its utility in patients with hypotension. It is an appropriate agent when cardiac output augmentation, not blood pressure support, is required and when a drop in peripheral resistance and preload is clinically tolerable or beneficial. Treatment of cardiogenic shock following myocardial infarction or cardiac dysfunction following shock and reperfusion typically requires support of myocardial contractility and reduction of peripheral resistance, which makes dobutamine an excellent choice in this setting.

Epinephrine. Epinephrine, the endogenous adrenal catecholamine, is released physiologically in response to stress. It has a broad spectrum of systemic actions, including significant cardiovascular effects. When epinephrine is administered as a pharmacologic agent (0.01 to $0.05 \mu\text{g/kg}$ per minute), β_1 -adrenergic effects predominate, causing increased stroke volume, heart rate, and contractility, along with modest β_2 -receptor stimulation. At higher infusion rates, α -adrenergic receptors are stimulated, which overcome β_2 -mediated peripheral vasodilation, resulting in an increase in blood pressure and SVR. Renal and splanchnic vasoconstriction, cardiac dysrhythmias, and increased myocardial oxygen demands limit the prolonged use of high-dose epinephrine. Transient increases in serum lactate have also been noted, possibly due to impaired regional blood flow. Epinephrine should be considered as a potential short-term agent for use in patients with impaired cardiac function not responsive to other agents such as dobutamine.

Norepinephrine. Norepinephrine, the sympathetic neurotransmitter, also has concentration-dependent cardiovascular effects. It should be considered as a drug with predominantly α -constrictor effects and less pronounced β -stimulation and is

therefore appropriate for use in patients who remain hypotensive despite dopamine administration or as a dopamine alternative. Combined α - and β -stimulation typically results in an increase in afterload and renal glomerular perfusion pressure, with preservation of cardiac output. Despite the potential for renal vasoconstriction, as a result of its effects on mean arterial pressure, norepinephrine is associated with an increase in urine output and creatinine clearance in hypotensive, and particularly septic, patients. A primary concern is to ensure adequate volume resuscitation prior to utilization due to risk of severe tissue damage from excessive vasoconstriction on the hypovolemic patient.

Isoproterenol. Isoproterenol is a synthetic catecholamine with potent α -adrenergic effects. From a cardiovascular standpoint, both cardiac and peripheral effects are significant. Stimulation of cardiac α_1 -receptors prompts an increase in contractility, heart rate, and conduction velocity. The chronotropic response, however, may predominate. These activities, in conjunction with peripheral vasodilation, generate significant increases in cardiac output and pulse pressure. Isoproterenol greatly increases myocardial oxygen demand and limits coronary filling due to tachycardia. As a result, indications for isoproterenol are limited to patients with hemodynamically significant bradyarrhythmias while preparations are made for electrical pacing.

Phenylephrine. Phenylephrine is a pure α -agonist and is an effective agent for increasing peripheral vascular resistance and arterial blood pressure. Although it has no direct effect on the myocardium, the increase in afterload increases left ventricular work and oxygen demand and may cause a decrease in stroke volume and cardiac output. It is often used as a first-line agent in patients with neurogenic shock, but its use is otherwise generally restricted to patients who remain hypotensive when the dosage of agents such as dopamine or norepinephrine cannot be increased due to excessive tachycardia.

Vasopressin. Vasopressin acts directly on V_1 receptors in vascular smooth muscle to cause vasoconstriction and increases the reactivity of vascular smooth muscle to catecholamines. Release of endogenous vasopressin is a normal physiologic response to shock. After septic or prolonged hemorrhagic shock, circulating vasopressin levels are decreased, possibly due to depletion of hypophyseal secretory stores. This relative deficiency may play a role in causing refractory hypotension. Vasopressin has minimal effects on normotensive patients, but in patients with septic shock it is effective in increasing SVR and mean arterial pressure. Vasopressin does not have inotropic properties but has potent splanchnic and coronary vasoconstrictors. It has been associated with decreased cardiac output due to myocardial ischemia and increased afterload and may worsen metabolic acidosis in patients in shock by causing splanchnic ischemia. As a result, early use of vasopressin at only physiologic concentrations to minimize associated other pressor use may be indicated.

Amrinone and Milrinone. Amrinone and milrinone are noncatecholamine inotropes with cardiovascular effects similar to dobutamine, but with minimal chronotropic activity. As steroidlike phosphodiesterase antagonists, they increase smooth muscle cyclic adenosine monophosphate (cAMP) and alter calcium metabolism. Cardiac contractility, stroke volume, heart rate, and cardiac output are increased, while a concomitant reduction in afterload offsets cardiac workload. The increase in cardiac performance with minimal demands on myocardial oxygen consumption offers some utility in the treatment of cardiogenic shock or as a potential alternative to dobutamine infusion. Both agents have a relatively long half-life of nearly 3 hours and should therefore be used with caution in patients at risk of developing hypotension, a major risk in the critically ill patient.

Vasodilators

Vasodilators are used as a means to augment cardiac function through optimization of preload and afterload, both of which reduce demands on the myocardium. The failing ventricle responds to afterload reduction with significant increases in stroke volume. The reason for this is that the compromised myocardium is working past the plateau and on the down slope of the Starling curve. As a result, afterload reduction with vasodilator agents may allow cardiac output to increase, resulting in improved oxygen delivery.

Nitroprusside. Nitroprusside is a balanced but potent arterial and venous smooth muscle vasodilator. It causes a reduction in afterload that increases cardiac output and has a less prominent venodilatory effect that reduces pulmonary venous pressure and preload. Hypotension may limit its use, particularly in the presence of contractility deficits or inadequate preload. Infusions ($>3 \mu\text{g/kg}$ per minute) continued for greater than 48 hours require monitoring of serum thiocyanate levels and arterial pH to detect complications of cyanide toxicity.

Nitroglycerin. Nitroglycerin is primarily a venous smooth muscle vasodilator, with less significant arterial vasodilation effects than nitroprusside. Thus, although nitroprusside predominantly decreases afterload, nitroglycerin predominantly increases venous capacitance. It is an effective treatment for acute myocardial ischemia because it reduces excessive preload and ventricular end-diastolic pressure, thereby diminishing myocardial oxygen demand.

Miscellaneous Therapeutics

Corticosteroids. In septic shock, ACTH resistance may diminish the normal cortisol response. Also, peripheral tissue resistance to corticosteroids may develop through proinflammatory-induced downregulation of normal corticosteroid receptors. Initial clinical trials showed no reduction in mortality when short courses of high-dose corticosteroids were used as adjuncts in the treatment of septic shock. However, recent studies utilizing low or physiologic doses ($<300 \text{ mg/day}$) of hydrocortisone for a longer duration (>5 days) of treatment have demonstrated a beneficial impact on mortality, particularly in septic patients.³³ Currently, routine use of ACTH stimulation tests is not advocated since they provide little more than prognostic information.³⁵ Given that hypoadrenal shock complicates various shock states, routine use is considered, but given the lack of proven benefit in other multicenter trials, use is currently not widely advocated without caution.³⁴

Activated Protein C. Decades of cellular and humoral inflammation research have failed to produce an effective immunologic intervention in humans with septic shock and organ failure. However, coagulation pathway dysfunction, the mediators of which are also part of the innate host response to infection, has recently been shown to correlate with disease severity and mortality. Specifically, septic shock is associated with rapid depletion of protein C and blunted endogenous protein C activation. The protein C pathway serves to regulate thrombosis and may play a role in limiting the inflammatory response and diminishing endothelial cell injury in response to inflammatory cytokines.

In a large randomized phase III trial of recombinant activated protein C (APC) in severe sepsis, a 6.1% absolute reduction in 28-day mortality compared with placebo was demonstrated. The short- and long-term survival rates associated with APC were significantly better only in septic patients at high risk of death. However, treatment with APC was also associated with a slightly increased risk of serious bleeding compared with placebo, particularly during infusion (3.5% vs.

2.0%), and must be considered a major contraindication in the patient in the early postoperative period or with minimal organ dysfunction in sepsis.⁹⁰

Metabolites and Electrolytes. Severe shock is frequently associated with hypocalcemia. Severe hypocalcemia that causes cardiac dysfunction or electrical instability should be rapidly treated. Calcium chloride rapidly corrects calcium deficits, whereas calcium gluconate must be degraded in the liver to release calcium ion, resulting in slower correction of deficits but less risk of tissue reaction. In the absence of evidence of cardiac dysfunction, attempts to restore plasma calcium to normal during shock are not warranted. Ischemia results in decreased cell membrane ATP and failure of the membrane calcium pump. Thus, reduced serum calcium levels during severe shock are probably due to movement of ionized calcium into the cells. Increased cytosolic calcium causes release of lysosomal enzymes and activation of phospholipases, protein kinases, and proteases that cause membrane damage and cytoskeletal destruction. Administration of exogenous calcium may merely worsen this uncontrolled intracellular calcium influx, whereas effective resuscitation will usually restore circulating calcium levels to normal.

Many shock resuscitation protocols emphasize correction of metabolic acidosis with fluids and inotropes until the pH begins to normalize. When interpreting an acid-base disorder, the presence of an anion gap is supportive evidence of lactic acidosis. However, a non-anion gap acidosis with worsening base deficit frequently occurs when normal saline is administered in large volumes. Efforts to correct a non-anion gap acidosis with additional fluids that may no longer be needed will only increase the risk of fluid overload.

Future Therapies

When initiating therapy for shock, the clinician does not know whether therapy has been started early, when salvage is still possible, or late, after irreversible changes have occurred within the cell and death is inevitable. Failure to respond to fluids, inotropes, and vasopressors with restoration of normal oxygen consumption and aerobic metabolism probably represents a defect in cellular and subcellular function in critical organ systems. There are many active areas of investigation that reflect the progression of our understanding of shock that have been outlined in this chapter and that have begun to move the field beyond the basics of fluid resuscitation and hemodynamic monitoring.

Efforts to control ischemia-reperfusion injury include controlled reperfusion with carbon monoxide or other compounds to reduce oxidative stress. Induced hypothermia may interrupt generation of harmful byproducts of ischemia and enable restoration of circulation and repair of structural injuries in a cellular environment where hypoxia is no longer critical. Additional biomarkers, such as procalcitonin, may allow earlier diagnosis and treatment of sepsis and shock.⁸⁶ New biosensors using near-infrared light may enable transcutaneous identification of critical limitations of blood flow and enable clinicians to more accurately target areas of regional hypoperfusion.⁹¹ A search for agents that optimize circulation in the microvascular system by preventing activation of the endothelium may enable resuscitative efforts to restore oxygen to cells as needed to maintain normal respiration and provide critical nutrients. Ultimately, further understanding of functional genomics may enable clinicians to target transcription and translational events triggered by shock and thus alter outcome.

CHAPTER 9 ■ CRITICAL CARE

AVERY B. NATHENS AND RONALD V. MAIER

KEY POINTS

- 1 Critical care units provide monitoring to identify and guide intervention prior to life-threatening physiologic deterioration and utilize advanced technology to support failing organs until treatment and recovery can occur.
- 2 Oxygen delivery to tissues must match cellular metabolic needs. To prevent cellular failure, adequate tissue oxygenation relies on oxygen-carrying capacity of blood (hemoglobin), loading of oxygen (gas exchange), and cardiac output (heart function).
- 3 When oxygen delivery is inappropriate to meet demand, fluid administration is often used to increase cardiac output through an increase in stroke volume. Conventional static indices of assessing fluid responsiveness are inferior to dynamic indices.
- 4 Respiratory dysfunction involves inadequate gas exchange, ventilation, or both. Oxygenation requires matching pulmonary perfusion to alveolar ventilation, whereas CO₂ excretion relies primarily only on ventilation. Ventilator support should be tailored to individual needs, and the ventilatory strategy may have a significant impact on outcome.
- 5 Excessive transfusion (hematocrit >21) has been shown to correlate with increased complications and mortality.
- 6 Full nutritional support (enteral route preferred) based on estimated needs should be provided as soon as possible. Carbohydrates should match metabolic needs to protect against excess nitrogen losses from protein breakdown. Essential fatty acids, vitamins, and mineral intake should recognize excessive losses in the critically ill.
- 7 Acute renal failure rarely occurs as an isolated organ failure. Dialysis is indicated for fluid overload, acidosis, electrolyte abnormalities, or coagulopathy. The choice of renal replacement therapy should be based on patient and institutional factors.
- 8 Multiple scores of critical illness have been developed to produce both an objective prognosis in the critically ill and an assessment of outcome by quantifying the severity of multiple organ failure.

ORGANIZATIONAL STRUCTURE OF THE INTENSIVE CARE UNIT

A significant proportion of patients under the care of surgeons receive some form of critical care during their hospital stay. The exposure to the intensive care unit (ICU) may take one of

several forms, ranging from routine postoperative monitoring in the high-risk surgical patient to the management of life-threatening postoperative complications. Additionally, many patients experience significant physiologic derangements due to their surgical illness (e.g., trauma, peritonitis) such that they require ICU care.

The ICU environment is conducive to the support of acute life-threatening organ dysfunction including the provision of

mechanical ventilation, renal replacement therapy, and invasive cardiac monitoring. These services require specific equipment and nursing expertise not found in or available throughout the hospital setting. As a result of these requirements, the ICU is typically spatially separated from the acute care beds in most hospitals. This spatial separation leads to one of two possibilities for the provision of medical care by physicians. The surgeon responsible for the care of the patient's underlying disease may assume primary responsibility for the provision of critical care services. This approach is in keeping with the ethical standards of the American College of Surgeons under which surgeons are responsible for the postoperative care of their patients. In this context, the ICU is simply a location where advanced monitoring and organ support are available. The surgeon continues with clinical responsibilities outside the ICU while also caring for critically ill patients. This organizational approach is typically referred to as an "open" ICU.¹ Alternatively, the surgeon may relinquish care of the patient to an intensivist who ideally may be specifically trained in the care of the critically ill patient and certified by one of several medical specialty boards including internal medicine, anesthesiology, or surgery. In this context, the intensivist has no other responsibilities outside the ICU that would limit his or her immediate accessibility and is primarily available to the critically ill patient. This organizational approach is often referred to as a "closed" ICU or an intensivist-model ICU.¹

The argument for maintaining the involvement of the operating surgeon as the primary physician responsible for the direction of critical care services is to ensure that there is continuity of care. Putatively, this continuity of care results in a well-defined, cohesive management plan that is necessary to ensure optimal outcomes. However, in a retrospective analysis of the effect of conversion from an open to a closed surgical ICU in a tertiary care academic center, complications and mortality were lower and the use of consultants was less frequent when patients were primarily cared for by surgeons or anesthesiologists who were board certified in critical care.² In another report in a similar surgical ICU setting, two different concurrent care models were compared. One group was managed exclusively by the critical care attending service and the other by the general surgery faculty and house staff. Despite increased severity of illness, the critical care cohort had a shorter ICU length of stay, fewer days of mechanical ventilation, fewer consultations, fewer complications, and lower hospital charges.³ Last, in a large observational study, Pronovost et al.⁴ evaluated outcomes following abdominal aortic surgery in the state of Maryland. This cohort of patients was well chosen because these individuals are at high risk of postoperative complications both related to the operative intervention and from significant comorbidity. These investigators demonstrated that daily rounds by a dedicated intensivist were associated with a significant reduction in the risk of postoperative complications and death.

Taken together, these data and a recent systematic review suggest that critically ill patients are best cared for by intensivists, but not at the total exclusion of the operating surgeon from decision making.⁵ For surgical patients, this argues for the continued training and involvement of surgeons in the field for optimal critical care. In the absence of a surgical intensivist, the most recent recommendations from the American College of Critical Care Medicine are that the intensivist and the surgeon proactively collaborate closely in the ongoing care of the patients.⁶

PURPOSES OF THE INTENSIVE CARE UNIT

- 1 The ICU serves several purposes. First, the availability of both electronic physiologic monitors and a high nurse-to-patient ratio (typically 1:1 or 1:2) provides an opportunity for very early detection of a critical change in status of the patient. This

change might relate to postoperative bleeding, the development of a neurologic deficit after craniotomy or spinal surgery (or injury to the brain or spinal cord), or changes in the patients' cardiorespiratory status. Common to all of these scenarios is a high likelihood of a need for urgent intervention. In this context, the ICU serves the purpose of monitoring to both identify and prevent adverse consequences in a patient at great risk.

The more familiar role of the ICU is an environment with all the resources available to support an acute deterioration of vital organ function. Approximately one third of all hospital costs are spent in the ICU environment, and with the exception of very specific clinical scenarios, most interventions studied appear to be cost-effective.^{7,8} To ensure optimal outcomes and efficiency, it is critical that the physician understands the physiology of organ dysfunction, the tools he or she has available for their monitoring and support, their limitations, and who most likely will benefit. Without this understanding, the physicians with the extensive resources available in the ICU have the potential to inflict great harm. The most frequent challenges in the critical care environment are the support of the failing cardiovascular system, lungs, and kidneys. During this period of support, the patient must receive adequate nutritional support until the acute physiologic derangements have normalized. The focus of this chapter is on these aspects of critical care, followed by a discussion of prognostic scoring systems and ethics in the ICU.

ASSESSMENT AND MANAGEMENT OF THE FAILING CARDIOVASCULAR SYSTEM

- 2 Support of the failing cardiovascular system is geared toward achieving adequate tissue oxygen delivery, which amounts to ensuring tissue oxygen delivery meets demand. Under normal conditions, oxygen consumption ($\dot{V}O_2$) is normally 100 to 120 mL/m² per minute, or 200 mL/min for a typical adult. The critically ill surgical patient experiences a profound increase in $\dot{V}O_2$ induced by high circulating levels of catecholamines and inflammatory mediators. Inadequate levels of tissue oxygen delivery in the face of either normal or increased levels of $\dot{V}O_2$ result in anaerobic tissue metabolism and are reflected clinically as a state of shock (i.e., cellular dysfunction). Currently, we have little control over tissue oxygen consumption, save for avoiding or treating hyperthermia and pharmacologic paralysis.

Oxygen Delivery

Many interventions in the ICU focus on manipulating tissue oxygen delivery ($\dot{D}O_2$) to meet either normal or elevated levels of tissue $\dot{V}O_2$. The amount of O₂ that is delivered to peripheral tissues is the product of the O₂ content in arterial blood (CaO₂) and the cardiac output. Normally, CaO₂ is about 20 mL/dL and the normal cardiac index (CI) is 3.2 L/m² per minute, or 5 L/min for a typical adult. Therefore, the normal systemic delivery of O₂ ($\dot{D}O_2$) is 20 mL/dL × 50 dL/min, or 1,000 mL/min. Although the O₂ content is the most important measure of O₂ in blood, it is the partial pressure of oxygen (PO₂) and the oxyhemoglobin saturation that are more commonly measured in the ICU. Each gram of hemoglobin (Hgb) can bind 1.36 mL of O₂. If the Hgb level of the blood is normal (15 g/dL) and the Hgb is 98% saturated, the amount of O₂ bound to Hgb is 19.9 mL/dL. In addition, a small amount of O₂ is physically dissolved in the water that makes up plasma and red blood cells. The solubility coefficient for O₂ is 0.0031 mL/mm Hg per deciliter; therefore, the amount of O₂ dissolved in 1 dL of blood at a PaO₂ of 100 mm Hg is 0.3 mL, so that the O₂ content of normal arterial blood is 19.9 + 0.3 or 20.2 mL/dL, conveniently rounded off to 20 mL/dL. Through the same arithmetic, the O₂ content of venous blood (CvO₂), which is 80%

FIGURE 9.1. The relation of O₂ content, saturation, and PO₂. Typical normal levels in arterial and venous blood are defined at various levels of hemoglobin. (After Bartlett RH. *University of Michigan Critical Care Handbook*. Boston, MA: Little, Brown; 1996.)

saturated, is 16 mL/dL; hence, the normal arteriovenous difference in O₂ content (avO₂ difference) is 4 mL/dL. Expressed mathematically:

$$\dot{D}O_2 = CI \times CaO_2$$

where: $CaO_2 = 1.36 \times Hsb + 0.0031 \times PaO_2$ CI = stroke volume \times heart rate and, therefore,

$$\dot{V}O_2 = CI \times (CaO_2 - CvO_2)$$

The relation among PO₂, saturation, and O₂ content for different concentrations of Hgb is shown in Figure 9.1. Note that the arterial partial pressure of oxygen (PaO₂) and saturations are the same as for normal arterial and venous blood due to an increase in CI, even though the O₂ content is severely decreased in anemia.

Relationship Between Oxygen Supply and Demand

Shock states are characterized by limitations in $\dot{D}O_2$ leading to a mismatch of oxygen supply and demand. For example, hemorrhagic shock leads to a reduction in preload (thus affecting stroke volume and CI) and a reduction in $\dot{D}O_2$, which is further decreased by the drop in CaO₂ due to loss of Hgb. The end result of this limitation in $\dot{D}O_2$ is tissue hypoxia, which is thought to play a causal role in the development of multiple organ failure. When $\dot{D}O_2$ falls below the level of $\dot{V}O_2$, $\dot{V}O_2$ becomes supply dependent and a state of anaerobic metabolism occurs.

The relation between $\dot{D}O_2$ and $\dot{V}O_2$ is reflected in the amount of O₂ in venous blood. Under normal conditions the amount of O₂ extracted is 20% of that delivered, with 80% of the O₂ still present in venous blood returning to the heart. This latter parameter, referred to as mixed venous oxygen saturation (SvO₂), is typically in the range of 70% to 80% and must be obtained from blood in either the right ventricle or pulmonary artery to allow mixing of superior vena caval, inferior vena caval, and coronary sinus blood as the relative rates of extraction in organs served by these circulations differ. In the critical care setting, SvO₂ is typically obtained from a pulmonary artery catheter (PAC) and can be monitored continuously using oximetric probes at the tip of the catheter. Reductions in SvO₂ are indicative of a mismatch between supply and demand. If $\dot{V}O_2$ increases with no further increase in delivery, then the percent of oxygen extraction must increase, resulting in a drop in SvO₂. More frequently, SvO₂ is affected by changes in $\dot{D}O_2$. Relatively small reductions in CI, arterial blood oxygen saturation (SaO₂), or Hgb concentrations can result in a significant drop in SvO₂. In the context of a very dynamic clinical situation with multiple perturbations occurring concurrently, continuous measurement of SvO₂ provides a good estimate of the net effect of any intervention on the balance between oxygen supply and demand.

In critically ill patients, $\dot{V}O_2$ is most frequently elevated compared to that seen during the normal state. $\dot{V}O_2$ is elevated in proportion to the degree of inflammation (either bacterial or sterile, as in burns and pancreatitis). A febrile patient with significant signs of sepsis typically has a $\dot{V}O_2$ that is 1.5 to 2 times normal. It is unusual for the $\dot{V}O_2$ of a critically ill patient to be more than twice normal. This occurs only in situations of severe muscular activity, as in seizures or tetany.

During this state of elevated tissue $\dot{V}O_2$, the normal response is a proportional increase in $\dot{D}O_2$; thus, it is normal for a hypermetabolic patient to have a high cardiac output and pulse rate, referred to as a hyperdynamic state. Not infrequently, patients cannot mount an increased $\dot{D}O_2$ in response to an increased $\dot{V}O_2$ because of any combination of hypoxia, anemia, and myocardial dysfunction. If this occurs, the amount of O₂ extracted from each deciliter of blood increases, reflected as a drop in SvO₂.

Hemodynamic Assessment

Given the importance of adequate oxygen delivery, it is evident that a tremendous amount of effort among intensivists is geared toward optimizing delivery. There are three important parameters that can be modified to affect systemic oxygen delivery: CI, Hgb, and hemoglobin saturation (SaO₂). While Hgb and SaO₂ are readily measured and manipulated, it is the monitoring (and subsequent manipulation) of CI that is most challenging. The cardiac output is a product of the stroke volume and heart rate. Most efforts at meeting tissue oxygen demands are directed toward increasing $\dot{D}O_2$ through an effect on stroke volume. Thus, the available tools in the critical care environment are geared toward understanding how stroke volume can best be manipulated to improve $\dot{D}O_2$.

- 3 The most common intervention to improve $\dot{D}O_2$ to reverse the shock state is through the administration of intravenous fluids. The sole reason for administering fluids is to increase the stroke volume. When fluids are administered, it is with the belief that the patient is on the steep part of the Starling curve and thus has preload-recruitable cardiac output (Fig. 9.2). In the ICU environment, there are two broad classifications of measures used to assess whether the administration of fluids will increase stroke volume (and thus cardiac output) (Table 9.1). While more frequently used, static indices of fluid responsiveness are generally less accurate than dynamic indices.

Static Indices of Fluid Responsiveness. Right atrial pressures as assessed through a central venous catheter are probably most frequently used as a measure of fluid responsiveness. It is generally believed that a low central venous pressure (CVP, reflecting a low right ventricular end-diastolic volume) reflects a low intravascular volume. It follows then that the administration of fluids in the context of a low CVP

FIGURE 9.2. The concept of preload-recruitable stroke volume is demonstrated. If the ventricle is on the steep part of the Starling curve (A), then a given increase in preload will lead to a significant increase in stroke volume. By contrast, on the flatter part of the curve (B), the stroke volume increases marginally if at all with the same increase in preload. Dynamic indices of preload-recruitable stroke volume are more accurate than static indices in identifying where on this curve the patient is at any point in time.

should increase stroke volume. However, a number of studies have demonstrated that the CVP is a poor marker of fluid responsiveness.^{9–11} In fact, it appears to be no more reliable than flipping a coin. Additionally, while many advocate that the change in CVP in response to a volume challenge might indicate fluid responsiveness, this index can also be unreliable. Thus, central venous catheters primarily serve the purpose of providing intravenous access. An oximetric central venous catheter has the additional advantage of providing the oxygen saturation level of blood in the superior vena cava. While this value overestimates mixed venous oxygen saturation, it might provide a useful parameter to evaluate the response to interventions as it trends well with the SvO_2 .^{12,13}

Other frequently measured static indices of fluid responsiveness are those measured through the use of the pulmonary artery catheter. The balloon-tip flow-directed pulmonary artery (or Swan-Ganz) catheter is inserted into the central venous system and is passed through the right heart and rests in the pulmonary artery where it provides continuous monitoring of pulmonary artery pressures. The catheter has more proximal ports such that central venous pressure is also monitored. Using the thermal dilution method, the catheter also provides information regarding CI. More recent modifications of the PAC have resulted in the capability of continuous measurement of cardiac output, SvO_2 , and right ventricular end-diastolic volume. When the balloon is inflated, the catheter advances slightly and wedges into a small pulmonary artery branch. This pulmonary

capillary wedge pressure (PCWP) provides an estimate of left ventricular end-diastolic pressure (LVEDP). The assumption is that a static, nonflowing column of blood that extends from the catheter's lumen to the pulmonary arterioles, capillaries, and veins of that lung segment provides a measure of the pressure downstream from the catheter tip ending in the left ventricle. Barring circumstances described later, LVEDP thus tracks left ventricular end-diastolic volume (LVEDV). LVEDV represents the volume of the left ventricle (i.e., myocardial stretch, or preload) that we aim to affect through increases in intravascular volume. If all assumptions are met, a patient with a low PCWP (and hence low LVEDV) should improve his or her stroke volume and thus his or her cardiac output with fluid administration. By contrast, if the PCWP is high, then cardiac output can only be improved through an increase in contractility or a reduction in afterload.

When the PCWP is used to guide administration of fluids, it is important to understand that several of the assumptions whereby PCWP tracks LVEDV might be violated. The ability to derive information regarding a volume (LVEDV) from a pressure (PCWP) first assumes that the myocardial compliance is normal. However, myocardial compliance is often affected by ischemia, massive volume resuscitation, high intra-abdominal or intrathoracic (e.g., high levels of positive end-expiratory pressure [PEEP]) pressures, or long-standing hypertension. Focusing on the PCWP to guide therapy in these circumstances will lead to an overestimate of preload. Mitral stenosis will also increase the PCWP, while LVEDV might be low. Not realizing the importance of these assumptions and how they might be violated often leads to incorrect treatment strategies.

Many have advocated the use of the right ventricular end-diastolic volume index (RVEDI), a measure of right ventricular filling, as a better measure to assess for adequate preload and fluid responsiveness.¹⁴ However, the relationship between volume responsiveness and either the PCWP or the RVEDI is very complex, and many recent studies suggest these may not be optimal indices to guide fluid management.^{9,10,15,16} Thus, the most reliable actionable information gleaned from the use of the PAC is limited to that assessed through measurement of the SvO_2 and from the CI.

The PAC is merely a monitoring device; thus, any benefit derived from its use will depend on the therapeutic strategies implemented following collection of various hemodynamic parameters. Despite the conceptual appeal of invasive hemodynamic monitoring and the information it provides, there are no data suggesting that the use of a PAC offers survival benefit.^{17,18} In several studies, the PAC has been associated with harm, including increased resource utilization, mortality, higher rates of renal failure, thrombocytopenia, and thromboembolic events.^{19,20} Given these data, it is important to realize that the PAC offers no clear significant benefit in the resuscitation of all critically ill patients. If there are specific subgroups that benefit, they have not yet been clearly identified in either retrospective or prospective studies. As a result of these findings, the use of the PAC by intensivists has dramatically declined.²¹

Dynamic Indices of Fluid Responsiveness. Dynamic assessments of fluid responsiveness are based on cyclical changes in systolic pressure, pulse pressure, and stroke volume in response to cardiorespiratory interactions.²² The increase in pleural pressure during a positive-pressure breath during inspiration reduces right ventricular preload and leads to a reduction in right ventricular stroke volume. The reduction in right ventricular stroke volume leads to a decrease in left ventricular filling after two to three heartbeats, a reflection of the pulmonary transit time (Fig. 9.3). This reduction in left ventricular filling then manifests as a reduction in left ventricular stroke volume, which is at its minimum during expiration.

These changes in stroke volume are more pronounced in the presence of hypovolemia, and this finding has been used to advantage to identify patients who might be fluid responsive.

TABLE 9.1

INDICES TO EVALUATE FLUID RESPONSIVENESS IN MECHANICALLY VENTILATED PATIENTS

■ STATIC INDICES	■ DYNAMIC INDICES
Right atrial pressure (measured as central venous pressure)	Systolic pressure variation
Pulmonary capillary wedge pressure	Pulse pressure variation
Right ventricular end-diastolic volume index	Aortic blood velocity ^a

^aEvaluable using Doppler echocardiography.

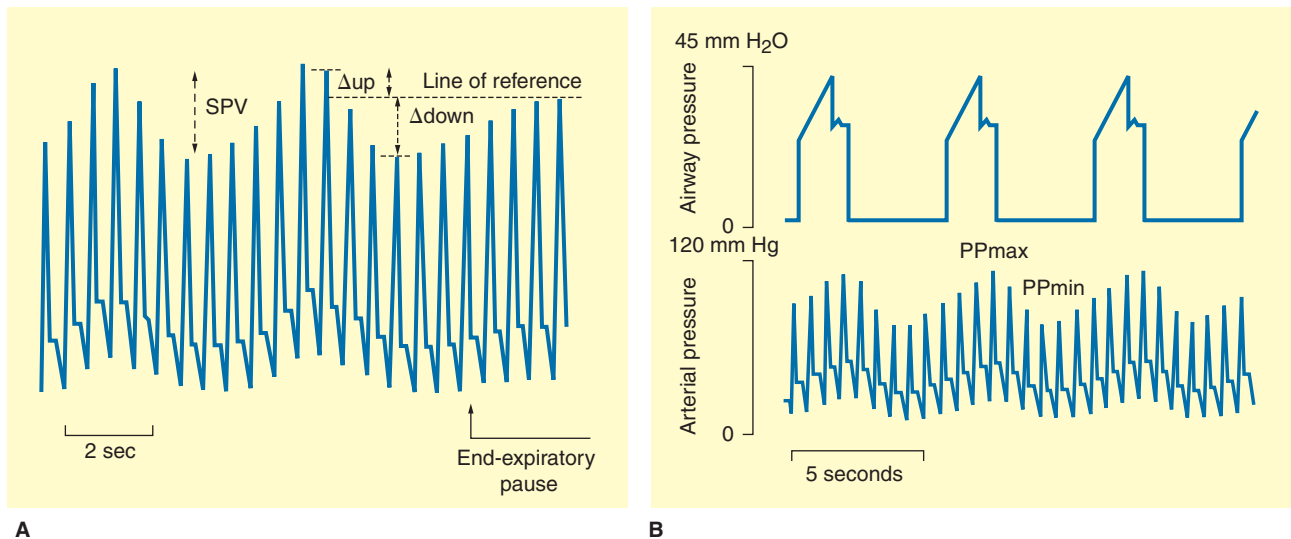

FIGURE 9.3. Demonstration of cyclic systolic (A) and pulse pressure variation (B) during the respiratory cycle of a mechanically ventilated patient. Systolic pressure variation (A) is demonstrated along with the reference line and end inspiration, from which Δ_{down} can be determined. Pulse pressure variation is demonstrated in B. The pulse pressure is greatest at the end of the inspiratory period and at least several beats later (during the expiratory period). (From Michard F, Teboul JL. Using heart-lung interactions to assess fluid responsiveness during mechanical ventilation. *Crit Care* 2000;4:282–289, with permission.)

Systolic pressure variation (SPV) is the difference between maximal and minimal values of systolic blood pressure during one positive-pressure mechanical breath (Fig. 9.3). SPV is divided into two components: Δ_{up} and Δ_{down} . Δ_{up} is the difference between the maximal value of systolic pressure over a single respiratory cycle and the reference systolic pressure. Δ_{down} is the difference between the reference systolic pressure and the minimal value of systolic pressure over a single respiratory cycle. In either case the reference systolic pressure is that pressure measured during an end-expiratory pause. SPV greater than 11% or Δ_{down} greater than 5 mm Hg has been most strongly associated with fluid responsiveness.²³

Pulse pressure variation has also been used as a dynamic index of fluid responsiveness and is directly proportional to left ventricular stroke volume (Fig. 9.3). Pulse pressure variation is measured as follows:

$$\Delta PP (\%) = 100 \times \frac{(PP_{max} - PP_{min})}{(PP_{max} + PP_{min})/2}$$

PPmax and PPmin are the maximal and minimal values of pulse pressure over a single respiratory cycle, respectively. Thus, ΔPP is simply the difference between PPmax and PPmin divided by the mean of the two values. A ΔPP (%) of greater than 13% is associated with fluid responsiveness and is believed to be more accurate than SPV.^{9,15,22}

One additional means of evaluating fluid responsiveness using Doppler echocardiography has been described. Echocardiography can be used to estimate aortic blood velocity, which is a good measure of left ventricular stroke volume. Respiratory variation in aortic blood velocity has been shown to be an accurate measure of fluid responsiveness, yet is more invasive than other approaches due to the need for an esophageal Doppler probe.²⁴

Esophageal probes, placed in a similar fashion to a nasogastric tube, measure blood flow velocity in the descending aorta by means of a Doppler transducer. The measured parameter is the aortic velocity waveform, which is converted to stroke volume using a standardized algorithm. An accurate velocity measurement requires good alignment between the Doppler beam and blood flow. In general, the agreement between cardiac output obtained by means of the thermodilution technique and that obtained through measurement of the aortic velocity waveform appears to be acceptable, but challenging.²⁵

Pulse contour analysis has also been investigated as a means to continuously monitor cardiac output. Pulse contour–derived cardiac output (PCCO) methods use the arterial pressure waveform as an input for a model of the systemic circulation to predict instantaneous flow. The pressure waveform is obtained from a peripheral arterial line (radial or femoral), which requires assumptions regarding the changes in pulse shape between these different locations. The values attributed to model parameters (e.g., arterial resistance and compliance) are initially estimated according to the patient's sex and age and from the pressure waveform. They are then refined following a calibration of mean cardiac output using an indicator technique (e.g., transpulmonary thermodilution or lithium chloride dilution). While there is good agreement between the cardiac output measured by thermodilution and that determined by pulse contour analysis, this technology has its limitations. PCCO appears to be inaccurate in the absence of sinus rhythm or in cases where the hemodynamic changes are occurring rapidly, as one might anticipate with hemorrhage or septic shock.^{26–28} Presumably, alterations in vasomotor tone affect the pulse contour to the extent that the algorithms begin to fail.

SUPPORT OF THE FAILING RESPIRATORY SYSTEM

Impending or established respiratory failure is a common reason for admission of surgical patients to the ICU. However, it is important to recognize that not all patients requiring an airway (endotracheal or nasotracheal intubation) and mechanical ventilatory support have respiratory failure. There are a large

New Modalities for Cardiac Output Measurement

The difficulties in using the PAC along with the questions regarding their safety has been the impetus for the development of several less invasive means of monitoring cardiac output.

proportion of patients who have airway instability requiring endotracheal intubation (postoperative patients, traumatic brain injury, intoxication) but whose need for mechanical ventilatory support is relatively limited. By contrast, patients with respiratory failure due to acute respiratory distress syndrome (ARDS), trauma, cardiogenic pulmonary edema, exacerbation of chronic obstructive pulmonary disease, or other less common etiologies require a mechanical ventilator to support gas exchange.

Pulmonary Gas Exchange

By gas exchange, we mean the process by which oxygen is taken up by the pulmonary capillaries from the alveolus and CO₂ ultimately excreted in each expired breath. These two processes—oxygen uptake and CO₂ excretion—are regulated by different mechanisms and have to be managed with these differences in mind.

Oxygen Uptake. Gas transfer in the lung and the causes of hypoxemia are demonstrated in Figure 9.4. Under normal conditions, red blood cells in the pulmonary capillaries become fully saturated and O₂ dissolves in the plasma; the result is a blood PO₂ of 100 mm Hg (when equilibrium is reached at the end of a resting expiration) and a saturation of 100% (alveolus A in Fig. 9.4). This equilibration may be disturbed by hypoventilation in relation to perfusion, or V/Q mismatch (alveolus B in Fig. 9.4); diffusion block caused by interstitial fibrosis or edema (alveolus C in Fig. 9.4); or perfusion of nonventilated alveoli (shunt), which is simply the extreme of hypoventilation (alveolus D in Fig. 9.4). Diffusion block and V/Q mismatch can usually be overcome by breathing 100% O₂; thus, persistent hypoxemia during exposure to high alveolar PO₂ is caused by total V/Q mismatch, called *transpulmonary shunting* or *venous admixture*. Under normal conditions, about 5% of the blood entering the left atrium has been shunted away from the pulmonary capillaries and oxygenation, either as a result of bronchial nutritive blood flow or through thebesian veins

FIGURE 9.4. Variables affecting pulmonary gas exchange while air is breathed. In alveolus A, blood flow and ventilation are equal and normal. The values in the alveolus and the exiting blood represent the end of a normal resting exhalation. Alveolus B represents hypoventilation. Alveolus C represents diffusion block. Alveolus D represents collapse or transpulmonary shunt. Alveolus E is ventilated without blood flow. (After Bartlett RH. Posttraumatic pulmonary insufficiency. In: Cooper P, Nyhus L, eds. *Surgery Annual*, 1971. New York: Appleton-Century-Crofts; 1971.)

FIGURE 9.5. The PaO₂ values achieved at variable levels of FiO₂ and variable levels of shunt. These calculations assume normal hemoglobin and a venous saturation of 75%. (After Bartlett RH. *University of Michigan Critical Care Handbook*. Boston, MA: Little, Brown; 1996.)

opening directly into the left side of the heart. This phenomenon, combined with the normal minor V/Q mismatch associated with shallow breathing at rest and positional effects on pulmonary blood flow, results in a normal arterial PO₂ of 90 to 100 mm Hg and a normal SaO₂ of 98%. The extent to which various degrees of transpulmonary shunting affect arterial oxygenation is shown in Figure 9.5. The shunt fraction is actually calculated by assuming that the blood in capillaries in those alveolar units that are functioning normally is fully saturated and oxygenated. In addition, it is assumed that the blood passing through areas of transpulmonary shunt is identical to venous blood. With these assumptions, the fraction of blood passing through the shunt can be calculated as the O₂ content of blood leaving the capillaries of normal alveoli minus the O₂ content of arterial blood divided by the O₂ content of blood leaving normal alveoli minus the O₂ content of venous blood.

Obviously, the effect of the O₂ content of venous blood in the shunt calculation is considerable; when O₂ delivery is decreased because of low cardiac output or a low Hgb concentration, the venous saturation falls and the shunt fraction is increased. It is not generally appreciated that the reductions in mixed venous oxygen saturation as a result of inadequate cardiac output or severe anemia might lead to profound hypoxemia refractory to increases in the fraction of inspired oxygen (FiO₂). This effect occurs only in the presence of some degree of intrapulmonary shunting and is not evident in patients with normal lungs. For example, if one assumes there is some degree of shunt due to atelectasis, blood perfusing the atelectatic lung mixes with blood perfusing the more normal lung, so that overall pulmonary venous oxygen content is significantly lowered. Increasing the inspired O₂ to 100% may result in a large increase in PO₂ in the blood leaving the normal lung but little increase in arterial oxygen saturation because the pulmonary venous blood from normal alveoli was already maximally saturated. The large increase in PO₂ is associated with a small increase in O₂ content because the O₂ that raises the PO₂ (e.g., from 100 to 500 mm Hg) does increase the small amount dissolved in plasma. However, the oxygenation of the arterial blood is an average of the O₂ content of blood from the two areas of lung, not an average of the PO₂. Therefore, systemic hypoxia persists regardless of the FiO₂. This physiology should be kept in mind—at times improvements in arterial oxygen saturation may only be gained through increasing O₂ by improving CI or Hgb concentration, both of which would serve to increase the mixed venous oxygen saturation.

TABLE 9.2**CALORIC VALUE OF METABOLIC SUBSTRATES**

RQ, respiratory quotient.

The shunt fraction can be calculated for any FiO_2 , but such a calculation will also include components of diffusion block and V/Q mismatch when the FiO_2 is less than 1. The level of lung dysfunction can be similarly estimated by calculating the alveolar–arterial (Aa) gradient for O_2 or the PaO_2 divided by the FiO_2 . The Aa gradient is calculated as follows:

$$\text{AaO}_2 \text{ gradient} = (P_B - P_{\text{H}_2\text{O}}) \times \text{FiO}_2 - \text{PaCO}_2/R - \text{PaO}_2$$

where P_B = barometric pressure (~60 mm Hg at sea level), $P_{\text{H}_2\text{O}}$ = 47 mm Hg at 37°C, and R = respiratory quotient (usually 0.8), and the alveolar PCO_2 is identical to the arterial PCO_2 .

With these assumptions, the normal Aa gradient is about 10 mm Hg, and an Aa gradient above 500 mm Hg corresponds to about 30% transpulmonary shunt. Dividing the PaO_2 by the FiO_2 is simply a shortened method to characterize the Aa gradient without all the calculations. The normal value is 500, and a value of 100 corresponds to a 30% shunt.

Finally, interruption of the blood flow to alveoli has no effect on oxygenation, except for the diversion of blood flow to all the other areas of lung (alveolus E in Fig. 9.4). If the remainder of the lung is basically normal, then occlusion of the pulmonary arteries should have no effect on oxygenation. Patients with pulmonary embolism can become hypoxic, however, because (a) blood flow must increase through areas of V/Q mismatch and shunting, (b) right atrial pressure increases to the point at which right-to-left shunting occurs through a patent foramen ovale, or (c) the residence time of red blood cells in pulmonary capillaries becomes so short that the time for oxygenation is inadequate. Of these causes, the latter can be largely corrected with supplemental O_2 , which raises the gradient for O_2 diffusion in the pulmonary capillaries. Thus, response to supplemental O_2 can aid in discriminating an obstructive process (e.g., pulmonary embolism) from a diffuse injury and increased shunt (e.g., ARDS).

Excretion of CO_2 . The rate of alveolar ventilation is the principal parameter affecting the excretion of CO_2 . This dif-

fers from oxygen uptake because CO_2 is much more diffusible than O_2 and a large amount of CO_2 is excreted during a short period of hyperventilation.

The total amount of CO_2 produced by systemic metabolism is roughly equivalent to the amount of O_2 consumed (100 to 120 mL/m² per minute, or 200 mL per minute in a typical adult). The ratio between CO_2 produced and O_2 consumed is referred to as the *respiratory quotient* (RQ) and varies slightly depending on whether carbohydrate or fat is being metabolized, with a normal value being 0.8. An RQ of 1 or greater suggests that the principal nutrient being metabolized is carbohydrate, whereas an RQ of 0.7 indicates that primarily lipids are being utilized (Table 9.2).

The production of CO_2 is increased or decreased by each of the factors that cause an increase or decrease in $\dot{\text{V}}\text{O}_2$. Most of the CO_2 in blood is present as bicarbonate ion, the amount of which cannot change quickly (somewhat analogous to the total blood Hgb or red cell mass in relation to O_2). The metabolically produced CO_2 , however, is mostly present as dissolved CO_2 , added to the blood in the peripheral tissues and excreted in the lung. In a steady state, the amount of CO_2 excreted through the lung is exactly equal to the amount of CO_2 produced in peripheral tissues. Because the amount excreted is so easily influenced by minor changes in ventilation, however, the assurance of a steady state is particularly important when $\dot{\text{V}}\text{O}_2$ is measured at the airway. The amount of CO_2 excreted is a function of ventilation of perfused alveoli (i.e., alveolar ventilation per minute, or minute ventilation). The relation between alveolar ventilation and CO_2 excretion is shown in Figure 9.6.

As excretion of CO_2 is directly related to alveolar ventilation, even if 70% to 80% of the alveoli are not inflated, hyperventilation of the remaining 25% can maintain normocarbia in arterial blood, whereas profound hypoxemia results from 70% to 80% shunt regardless of the level of FiO_2 or ventilation of the remaining alveoli. These relations are shown in Figure 9.7, which again illustrates that oxygenation is a function of matching blood flow to alveolar inflation, whereas CO_2 excretion is a function of ventilation or hyperventilation of alveoli with some blood flow. Normally, the end-tidal CO_2 represents mixed alveolar gas that is in equilibrium with pulmonary capillary blood and hence with arterial blood. Therefore, the end-tidal CO_2 and the partial pressure of arterial carbon dioxide (PaCO_2) should be almost identical. The central respiratory center is very sensitive to the PaCO_2 , so that the automatic rate and depth of breathing are regulated to maintain the PaCO_2 at 40 mm Hg. The end-tidal CO_2 should be the same or just slightly less. There is no way that the PaCO_2 can be lower than the end-tidal CO_2 . If some of the end-tidal gas has not been in equilibrium with pulmonary capillary blood, the gas does not contain CO_2 and the CO_2 is diluted in end-tidal measurements, so that the end-tidal CO_2 is lower than the PaCO_2 . This situation occurs whenever a significant amount of lung is ventilated but not perfused (i.e., dead space)

FIGURE 9.6. Alveolar ventilation required to excrete different levels of metabolically produced CO_2 . (Adapted from Nunn JF. *Applied Respiratory Physiology*. London: Butterworth-Heinemann; 1969;2:9.)

FIGURE 9.7. The effects of collapsed alveoli (transpulmonary shunt) on the exchange of O_2 and CO_2 in the lung. **A:** Exchange of CO_2 is limited by ventilation of perfused lung. **B:** Exchange of O_2 is limited by blood uptake of O_2 in ventilated lung. (After Bartlett RH. Pulmonary pathophysiology in surgical patients. *Surg Clin North Am* 1980;60:1323.)

or is overventilated and minimally perfused or when some of the end-tidal gas represents inflation gas that is simply compressed and released, never having reached the alveoli. The latter situation inevitably occurs under any positive-pressure ventilation circumstance but creates a significant end-tidal $PaCO_2$ gradient only when peak airway pressures are very high and when the compression volume is a significant component of each exhaled breath. However, the end-tidal CO_2 measurement becomes a useful continuous monitor of $PaCO_2$ when the lung is nearly normal, as in ventilator weaning. In addition, the gradient between end-tidal and arterial CO_2 , when it is large, serves as an indirect measure of nonperfused alveoli (dead space) or compression volume, or both.

Pulmonary Mechanics

The interrelations of gas volumes and pressures in ventilation are referred to as *pulmonary mechanics*. How these volumes and pressures relate depend on pulmonary compliance. The standard compliance or volume–pressure curve, shown in Figure 9.8, is drawn by measuring volume and pressure at stages of lung *deflation* after total inflation. Volume–pressure curves for normal lungs in three different patients are shown in Figure 9.8. Notice that the curve for a normal 35-kg child is the same as that for an adult with major atelectasis. (It would be similar after pneumonectomy in an adult.) This emphasizes the point that the functional lung in acute respiratory failure is smaller, but not necessarily “stiffer.” Computed tomographic studies of patients with ARDS support this concept. The lung injury in ARDS is heterogeneous such that, in the presence of normal tidal volumes, the relatively few alveoli that remain ventilated might very well be overdistended.²⁹ These findings have significant implications for iatrogenic injury and ventilatory strategies in these patients.

In the example shown in Figure 9.8, inflation of the normal lung with 500 mL of gas requires a pressure of 8 cm H_2O and

FIGURE 9.8. Volume–pressure (compliance) curves representing a normal lung (A and B) and an atelectatic or edematous lung (C through E). The functional reserve capacity is decreased (A to C), and more pressure is required for inflation (C to E). (After Bartlett RH. Use of mechanical ventilation. In: Holcroft J, ed. *Care of the Surgical Patient, Vol 1. Critical Care*. New York: Scientific American Medicine; 1989;2:9.)

moves the patient from point A to point B. When the pressure is released, exhalation occurs passively, and lung volume returns to point A. Periodic inflation to 25 or 30 cm H_2O would achieve near-total alveolar inflation without causing overdistention. In acute respiratory failure, the cause of decreased compliance is almost always associated with a decrease in the functional residual capacity (FRC) (Fig. 9.8). The decreased FRC represents lost alveoli, which are either collapsed or filled with fluid but still perfused with blood. Because the lung is smaller, the compliance curve is shifted to the right, and much higher pressures are required to achieve the same level of inflation. To inflate the lung to point E, for example, a pressure of 40 cm H_2O would be necessary. One way of managing ventilation in this circumstance is to maintain PEEP at 10 cm H_2O (C' in Fig. 9.8) and ventilate to point D with tidal breathing. The PEEP is set at this level to maintain the inflation of alveoli that might close at lower end-expiratory pressures. The elevated inspiratory pressures on top of the PEEP may also be helpful in recruiting closed alveoli. When that happens, the functional lung is bigger, and the entire compliance curve shifts back toward the left.

PEEP has beneficial effects on gas exchange and lung compliance; however, if used without understanding the potential downsides, it can cause harm. For example, high levels of PEEP in relatively compliant lungs might increase intrathoracic pressure sufficiently to inhibit venous flow and reduce preload and cardiac output. High intrathoracic pressures might also have dramatic effects on patients with elevated intracranial pressure due to increased impedance for cerebral venous return. Caution must also be exercised in patients with a unilateral lung process (e.g., aspiration, pulmonary contusion, alveolar hemorrhage), as the increased pressures might harm the uninjured normal lung through overdistention.

Several measurements must be taken to determine whether positive airway pressure is recruiting collapsed alveoli or simply distending normal alveoli (Fig. 9.9). As the most normal areas of lung have the best compliance, they are the most vulnerable to overdistention, and this vulnerability contributes to the steady progression of lung dysfunction in patients ventilated at either excessive pressures or tidal volumes. As collapsed alveoli are reinflated, compliance improves and oxygenation increases at the same ventilator settings as shunt decreases. These principles and measurements must be kept in mind during the treatment of the patient on a mechanical ventilator.

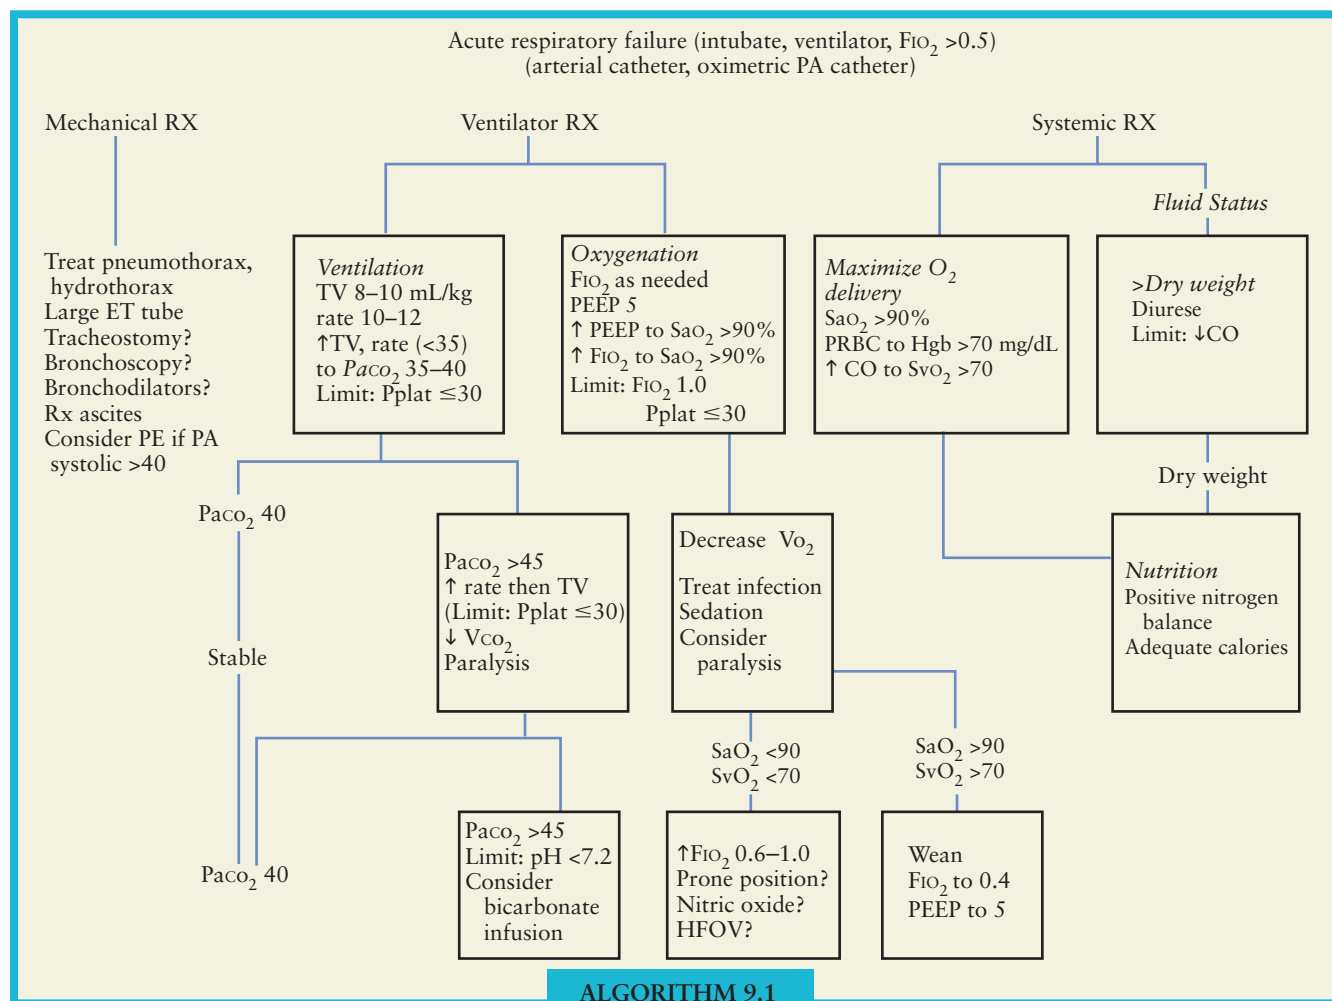

FIGURE 9.9. During mechanical ventilation, the gas volume may inflate alveoli equally (recruitment) or overdistend selected alveoli (distention). (After Bartlett RH. Pulmonary pathophysiology in surgical patients. *Surg Clin North Am* 1980;60:1323.)

Management of Respiratory Failure

When confronted with a patient in acute respiratory failure, the first priority is to identify and treat easily remediable causes. Examples include a pneumothorax requiring a chest tube, acute pulmonary edema requiring diuresis, or an acute asthma exacerbation that may respond to bronchodilator therapy. In the absence of a readily reversible cause, most patients will require mechanical ventilatory support (Algorithm 9.1). Setting up the ventilator can be intimidating because the terminology is complex and continues to evolve with advances in technology. Only the most commonly used modes will be discussed.

4 In principle, three parameters determine the mode of ventilation: *trigger*, *limit*, and *cycle*. Trigger refers to the signal to initiate the inspiratory phase and is set according to whether or not the patient has spontaneous respiratory effort. Mandatory modes such as continuous mandatory ventilation (CMV) use a time trigger, whereas spontaneous modes such as pressure support use a flow or pressure change initiated by the patient. Mandatory modes of ventilation are required if the patient has inadequate or no spontaneous respiratory effort.

The limit variable refers to the flow or pressure that is set during inspiration and cannot be exceeded. By convention, if the limit variable is flow, then the mode is labeled volume control (VC) ventilation (volume = flow × time). Alternatively, if

ALGORITHM 9.1

ET, endotracheal; PA, pulmonary artery; PCWP, pulmonary capillary wedge pressure; PE, pulmonary embolism; PEEP, positive end-expiratory pressure; PRBC, packed red blood cells; TV, tidal volume. (Modified from Bartlett RH. *University of Michigan Critical Care Handbook*. Boston, MA: Little, Brown; 1996.)

the limit variable is pressure, then the mode is termed pressure control (PC) or pressure support ventilation (PSV). Although both are pressure-limited modes, PSV requires spontaneous inspiratory effort, whereas PC can be used as either a mandatory or spontaneous mode.

Cycle is the variable that terminates the inspiratory cycle, which might be time, flow, pressure, or volume. In general, setting the cycle variable is equivalent to setting the inspiratory time and is manipulated based on pulmonary mechanics and the desired ratio of inspiratory to expiratory time. Intermittent mandatory ventilation (IMV) and assist control (A/C) modes both represent forms of volume control ventilation in which breaths are delivered at a set tidal volume with a set frequency. In A/C mode, if the patient initiates a breath, the tidal volume delivered will be the set volume, whereas in IMV mode, the tidal volume of spontaneous breaths is determined by the patient. However, when the ventilator is triggered (machine or patient), a fixed flow of gas is generated for a specific time providing a preset inspiratory volume (volume = flow \times time). Volume-limited ventilation is generally easier to regulate but may be less comfortable for the awake patient as the flow curve is a square wave and markedly different from the normal inspiratory flow pattern in a nonventilated patient. The major advantage of volume-controlled modes of ventilation is the assurance that the patient will receive a guaranteed minimum minute ventilation.

PSV is the most frequently used form of pressure-limited ventilation. In this mode, the patient triggers a breath and a variable flow is delivered to meet a set pressure. Cycling in this mode is determined by the decrease in flow rate and causes the ventilator to stop the inspiratory phase. As the lung inflates, compliance decreases and flow decreases to maintain a constant inspiratory pressure. When flow reaches a percentage of the maximal flow rate (typically around 80% of maximum, depending on the ventilator model), inspiratory flow ceases, and the patient exhales passively. Tidal volumes will be determined by lung compliance—the more compliant the lung, the larger the tidal volume is at a set pressure. PSV is often used as a partial mode of ventilatory support in alert patients who may not tolerate more controlled forms of mechanical ventilation.

Pressure control ventilation (PCV) is related to pressure support in that the flow is descending in amplitude during the inspiratory cycle. In contrast to PSV, with PCV the inspiratory time is set by the ventilator, not the patient. PCV is generally used in the A/C, which allows full support of patient-initiated breaths in addition to those initiated by the ventilator (mandatory, or time triggered). The purported advantages of PCV relate to the decelerating flow curve, which is thought to allow more time for alveolar inflation and gas exchange. It is important to recognize that the tidal volume (and therefore minute ventilation) might change quite rapidly with changes in lung

compliance. Thus, without continued reassessment of tidal volumes, there is a possibility that the patient might be significantly hypo- or hyperventilated. Pressure-regulated volume control (PRVC) is a mode similar to PCV in which the pressure is autoregulated (within a specified range) to ensure tidal volumes are maintained despite changes in lung compliance.

Ventilator Strategies. Endotracheal intubation and mechanical ventilation provide vital support yet are associated with disadvantages, including a greater risk of pneumonia and aggravation of alveolar injury, respectively. Additionally, there is increasing evidence that the manner by which patients are ventilated and weaned might have significant effects on outcome. For example, in a large randomized controlled trial, patients with ARDS or acute lung injury (a form of hypoxemic respiratory failure, Table 9.3³⁰) ventilated with lower tidal volumes (6 mL/kg) had a significantly lower mortality than those ventilated at higher tidal volumes (12 mL/kg).³¹ Clinical and experimental studies suggest that higher tidal volumes lead to ventilator-induced lung injury (by means of overdistending alveoli), which incites a secondary greater local and systemic inflammatory response. Patients ventilated with lower tidal volumes also had significantly lower ventilatory pressures (plateau pressures <30 cm H₂O); thus, it is unclear which offered benefit—the lower tidal volumes or the lower plateau pressures. Most centers have since adopted this lung-protective ventilatory strategy.

A frequent point of controversy in managing the hypoxemic patient is the relative merits of using high levels of PEEP and lower levels of FiO₂ or using lower levels of PEEP with a correspondingly higher FiO₂. By convention, many intensivists use higher levels of PEEP to maintain the FiO₂ less than 0.6, believing that higher levels of oxygen might induce hyperoxic lung injury. However, results from a randomized controlled trial comparing a high PEEP strategy with a high FiO₂ strategy demonstrated similar outcomes.³² Given these data, the risks and benefits of using PEEP should be assessed for each patient depending on the nature of his or her underlying lung disease and associated conditions (e.g., low cardiac output state, high intracranial pressure, unilateral lung disease).

Refractory hypoxemia in the critically ill patient often presents a significant challenge. Two common approaches to assist in the management of these patients are prone positioning and high-frequency oscillatory ventilation (HFOV). Prone positioning requires that the patient be cared for in this position, typically for as few as 4 to as many as 24 hours a day for as long as 1 to 10 days, depending on the clinical response. This approach results in improved ventilation due to the triangular shape of the rib cage (wider posteriorly) and a reduction in atelectasis by reversing the compressive effects of the heart and

TABLE 9.3

RECOMMENDED CRITERIA FOR ACUTE LUNG INJURY AND ACUTE RESPIRATORY DISTRESS SYNDROME^a

	■ TIMING	■ OXYGENATION	■ CHEST RADIOGRAPH	■ PULMONARY ARTERY WEDGE PRESSURE
Acute lung injury (ALI)	Acute onset	PaO ₂ /FiO ₂ ≤ 300 regardless of PEEP level	Bilateral infiltrates on frontal chest radiograph	≤ 18 when measured or no clinical evidence of left atrial hypertension
Acute respiratory distress syndrome (ARDS)	Acute onset	PaO ₂ /FiO ₂ ≤ 200 regardless of PEEP level	Bilateral infiltrates on frontal chest radiograph	≤ 18 when measured or no clinical evidence of left atrial hypertension

PEEP, positive end-expiratory pressure.

^aIn setting of known risk factors of either direct lung injury (aspiration, diffuse pulmonary infection, near drowning, toxic inhalation, pulmonary contusion) or indirect lung injury (sepsis, severe nonthoracic trauma, massive transfusion, cardiopulmonary bypass or ischemia/reperfusion insult). Adapted from Bernard GR, Artigas A, Brigham KL, et al. The American-European Consensus Conference on ARDS. Definitions, mechanisms, relevant outcomes, and clinical trial coordination. *Am J Respir Crit Care Med* 1994;149:818–824.

diaphragm due to gravitational forces.³³ The prone position also improves the clearance of secretions. Persistence of improved perfusion to the posterior lung also improves perfusion/ventilation mismatch. In several clinical trials, prone positioning led to a 25% to 35% increase in the $\text{PaO}_2/\text{FiO}_2$ ratio, with sustained effects even beyond the period of proning.³⁴ Rates of pneumonia appear to be significantly lower due to a lesser risk of aspiration of secretions. While this approach appears to have significant merit, patient selection is important. Trauma patients in whom there are concerns regarding the stability of the spine are not appropriate, nor are patients at risk for cardiac arrest due to the challenges in performing cardiopulmonary resuscitation (CPR). In addition, to date, no overall benefit to survival has been demonstrated.

HFOV is a mode of ventilation using a piston pump oscillating at frequencies between 180 and 600 breaths/min (3 to 10 breaths/s). This piston pump moves air with very low tidal volumes (40 to 200 mL). Mean airway pressures are typically set just above the mean airway pressures used for conventional ventilation, yet the high frequency and lower tidal volumes lead to better lung recruitment and a higher end-expiratory lung volume as the alveoli do not have an opportunity to collapse. There is less cyclical recruitment-derecruitment of alveoli, leading to less alveolar shearing. At the same time, the lower tidal volumes prevent overdistention. Taken together, this mode of ventilation should reduce the potential for ventilator-induced lung injury, a finding demonstrated in small animal studies.³⁵ While large randomized controlled trials evaluating the efficacy of HFOV in patients with acute lung injury are under way, early studies suggest an improvement in $\text{PaO}_2/\text{FiO}_2$ ratios and a lower mortality rate.³⁶

Weaning from Mechanical Ventilation. The process of weaning from the ventilator has changed significantly with evidence that the most rapid means of liberating a patient from the ventilator is through daily trials (30 to 90 minutes) of spontaneous breathing with low levels of continuous positive airway pressure (CPAP). This approach is superior to the gradual withdrawal of ventilation using pressure support or IMV.^{37–39,40} If the patient tolerates the trial of spontaneous breathing, it is likely that he or she can be extubated with a low risk of requiring reintubation, providing he or she can protect the airway. Patients who fail a trial of spontaneous breathing should be rested for at least 24 hours using a stable, nonfatiguing form of ventilatory support. A partial support mode of ventilation (e.g., pressure support) probably offers benefit in terms of patient comfort while allowing a period of rest, as the patient can determine the respiratory rate, flow rate, inspiratory time, and tidal volume.

TRANSFUSION THERAPY IN THE INTENSIVE CARE UNIT

Virtually half of patients admitted to an ICU will receive a transfusion during the course of their ICU stay.⁴¹ In those staying in the ICU for at least 1 week, 85% will require an average of 9 units over the course of their ICU stay.⁴² The causes are multifactorial and include blood loss from the underlying disease(s), repeated blood draws for laboratory tests, and suppression of erythropoietin release and erythropoiesis. In the past, transfusions were provided liberally to maintain Hgb in the range of 10 g/dL with the belief that allogeneic transfusions were not harmful and would improve oxygen delivery to hasten recovery. However, many studies have demonstrated that tissue oxygen extraction is not improved following transfusion. This lack of enhanced tissue oxygenation is likely multifactorial and, in large part, related to the effects of storage on the erythrocyte. These effects result in increased hemoglobin oxygen affinity (due to loss of 2,3-diphosphoglycerate) and

changes in membrane deformability leading to sludging in the microvascular circulation.^{43–45} Additionally, a systematic review of cohort studies suggests that the transfusion of allogeneic red blood cells is associated with an increased risk of nosocomial infection, acute lung injury, and multiple organ failure.⁴⁶ It is noteworthy that these sequelae are not limited to allogeneic red blood cells, as they have also been strongly associated with the transfusion of fresh frozen plasma.^{47,48}

5 A large clinical trial in which nonbleeding, euvolemic critically ill patients were randomized to either a liberal transfusion strategy (Hgb of 10 g/dL) or a restrictive strategy (Hgb of 7 g/dL) demonstrated that patients in the liberal group fared no better than those in the restrictive group who received far fewer transfusions.⁴⁹ In fact, younger patients (younger than 55 years of age) and those with Acute Physiology and Chronic Health Evaluation (APACHE) II scores of less than 20 had lower mortality and lower rates of organ dysfunction. In a subset of patients requiring prolonged ventilator support, the rate of liberation from mechanical ventilation was higher in patients randomized to the restrictive arm, suggesting there is no benefit to transfusing patients for the purposes of improving their ability to wean off the ventilator.⁵⁰ It appears that the risk of adverse outcomes related to a strict transfusion strategy is higher only in patients with unstable cardiovascular disease (unstable angina or acute myocardial infarction).⁵¹

Several approaches may be used to reduce transfusion requirements in the critically ill patient. Blood sampling should be reduced to only that which is required to alter patient care. Pulse oximetry should be used rather than arterial blood gases when there are changes in PEEP or FiO_2 , and end-tidal CO_2 monitoring can guide changes in minute ventilation. Weekly recombinant human erythropoietin (rHuEPO) administration has been evaluated in patients with an anticipated prolonged ICU stay. In one randomized controlled trial, erythropoietin reduced transfusion requirements by approximately 20% and reduced the need for any transfusion by 17%, without affecting length of stay, rates of organ dysfunction, or mortality.⁵² A subsequent meta-analysis of seven randomized controlled trials suggested a 0.4-unit reduction in red cells transfused and a 25% lower risk of receiving any transfusion.⁵³ Again, no effects on clinically relevant outcome were evident. Given these findings of limited benefit, erythropoietin receptor agonists are not recommended for use in critically ill patients. Further, the incremental cost-effectiveness with the use of these agonists is unacceptable. Estimates include almost \$5 million to prevent one transfusion-related adverse event.⁵⁴

METABOLISM AND NUTRITION

Metabolic and nutritional support are vital if the critically ill patient is to survive the ICU stay. Depletion of energy and protein reserves leads to an inability to wean off the ventilator, immunologic failure, and a high probability of death due to overwhelming infection. Thus, in the ICU a tremendous amount of effort is geared toward assessing and maintaining adequate nutritional support.

Energy Sources

The major sources of energy are carbohydrates (including ketones and alcohols) and fats. In addition, protein can be oxidized through gluconeogenesis and is often a significant source of energy in critically ill patients. The goal of nutritional support is to supply energy from sources other than protein, so that endogenous and exogenous protein can be used for anabolism rather than catabolism. In normal volunteers and surgical patients, the breakdown of protein is decreased by giving the

subject exogenous fuel, typically in the form of carbohydrate or fat. This is referred to as the *protein-sparing effect*. Small amounts of glucose (400 cal/d) provide some degree of protein sparing, but full caloric support is required for maximal effect.

Carbohydrate is the major source of energy during the normal, nonstarving state. The brain and red cells are obligate users of glucose. They require glucose as the primary energy source under normal conditions. Other organs also use glucose preferentially as a source of energy. The brain and red blood cells can develop the capacity to use ketones as an energy source, a process called *starvation adaptation*. When fully oxidized, carbohydrate produces 4 cal of energy per gram of substrate metabolized, 5 cal of energy per liter of O_2 consumed, and one molecule of CO_2 for each molecule of O_2 consumed. The latter ratio is the RQ, discussed previously in the context of CO_2 production (see Table 9.2).

Fat is the most efficient source of energy. Fat produces 9 cal of energy per gram of substrate metabolized and 4.7 cal of energy per liter of O_2 consumed in this oxidation; its RQ is 0.7. Fat is stored as triglyceride, and for every three molecules of fatty acid oxidized to produce energy, one molecule of glycerol is also oxidized. Endogenous fat is the major source of energy during starvation. Glycogen stores are virtually depleted after a single day of fasting, following which fat becomes the major source of energy, with protein breakdown supplying glucose through the process of gluconeogenesis.

Metabolic Requirements

The typical expenditures of energy and protein in normal subjects and critically ill patients are shown in Figure 9.10. Protein and energy requirements are continuous. These are met by endogenous sources during fasting or through exogenous treatment (nutrition). Energy expenditure is referred to as the *basal metabolic rate*, or the *basal energy expenditure*. The term *basal metabolic rate* describes the energy required to maintain cell integrity in the resting state and at thermoneutrality. The latter term means an ambient temperature, usually close to 80°F (28°C), at which the heat loss and the need for increased heat production to maintain the body temperature are minimal. The basal energy expenditure (BEE) decreases with advancing age and varies with sex and body size. It is a function of cellular metabolism and hence of the body cell mass. The basal energy expenditure (in kilocalories)

is usually estimated from the Harris-Benedict equation, which incorporates age, sex, and body size:

Women:

$$BEE = 655 + (9.6 \times \text{weight in kilos}) + (1.8 \times \text{height in cm}) - (4.7 \times \text{age in years})$$

Men:

$$BEE = 66 (13.7 \times \text{weight in kilos}) + (5 \times \text{height in cm}) - (6.8 \times \text{age in years})$$

Requirements are most often expressed as kcal/kg per day. Basal requirements in healthy adults are typically in the range of 25 kcal/kg per day.

Estimating and Measuring Energy Requirements

The actual metabolic rate of any given patient can be estimated by modifying the predicted basal rate according to the clinical condition. For example, the metabolic rate is decreased by 10% in a starving person and increased by 10% with minor activity. This further estimation of metabolic activity in the resting (as opposed to basal) state is referred to as the *resting energy expenditure*. Trauma, stress, sepsis, and surgical operations are all known to increase the metabolic rate. As a result, the BEE is usually multiplied by a stress factor to better approximate caloric requirements (Table 9.4). In general, to match utilization, the critically ill patient requires approximately 35 kcal/kg per day.

Although most of the studies on nutrition in critical illness have been based on estimated energy expenditure, actual measurement is much more accurate and is an important aspect of critical care. The most commonly used method of measurement is indirect calorimetry. In the ICU, indirect calorimetry is the only accurate and clinically feasible method of measuring energy expenditure. It is called indirect because the caloric burn rate is calculated from a measurement of oxygen uptake. Direct calorimetry implies a measurement of heat released by the body, which is technically difficult and clinically impractical. Indirect calorimetry relies on the fact that burning 1 kilocalorie requires approximately 200 mL of oxygen. Because of this very direct relationship between caloric burn and oxygen consumed, measurements of oxygen uptake (VO_2) and caloric burn rate are virtually interchangeable.

FIGURE 9.10. Energy and protein metabolism in normal, starving, operative, and septic states. (After Bartlett RH. Nutritional support. In: Dantzker DR, ed. *Cardiopulmonary Critical Care*. Orlando, FL: Grune & Stratton; 1986:263.)

TABLE 9.4

PREDICTED INCREASE IN CALORIC REQUIREMENTS AS A FUNCTION OF STRESSOR

20%–30% BSA	1.5
40% BSA	1.75
>50% BSA	2.0

BSA, body surface area.

Indirect calorimetry can be carried out at the patient's bedside and requires the measurement of the differences in oxygen and carbon dioxide concentrations between a known volume of inspired and expired gas. Assuming the patient is in a steady state, oxygen consumption and carbon dioxide production can be quantitated. With measurement of O_2 consumption and CO_2 production, the RQ ($VCO_2/\dot{V}O_2$) can be calculated, thus also providing an assessment of the relative oxidation of carbohydrates and fat (see Table 9.2). Thus, indirect calorimetry provides some indication of which substrates are being utilized to fulfill energy requirements. Normally the RQ is approximately 0.8; very infrequently the RQ might be in excess of 1 and as high as 2.5, indicative of lipogenesis (synthesis of fat from carbohydrates) and indicative of excess availability of carbohydrates.

Measurement of the RQ is helpful as an internal check on the accuracy of the calorimetry measurements and as a guideline to patient management. For example, if a patient has been receiving only 500 cal/d and has a metabolic rate of 2,500 cal/d, one would expect that the use of fat would be maximal, and the RQ should be 0.7 or less. If such a patient is treated with parenteral nutrition and glucose used as the major source of energy, the RQ should be 1 when the caloric replacement matches caloric losses. If the RQ exceeds 1, then some of the excess infused carbohydrate is being converted to fat and excess CO_2 is produced, which leads to a need for a higher minute ventilation. Thus, hypercaloric feeding with glucose can aggravate respiratory failure and the requirement for mechanical ventilation simply by increasing the load of CO_2 .

Protein Metabolism

Estimating and Measuring Protein Requirements. In normal protein metabolism, a continuous excretion of nitrogen (mostly as urea) equivalent to about 50 g of protein each day is matched by a protein intake of 50 g/d. The rate of protein synthesis and breakdown is about 300 g/d, with most endogenous amino acids being recycled into new protein. In starvation, protein catabolism continues (although at a slower rate) without a corresponding protein intake, leaving the patient in a negative protein balance. This protein flux is most conveniently measured as nitrogen flux; consequently, the condition is commonly referred to as *negative nitrogen balance*. During critical illness, the rate of protein catabolism generally increases while intake stops, so that a significant negative nitrogen balance results. It is convenient to think of this protein breakdown as necessary to produce critically required glucose through gluconeogenesis when other carbohydrate stores have been exhausted.

Protein Sources. The fact that the nitrogen balance is negative does not mean that protein synthesis stops or slows down. On the contrary, the synthesis of new cells, inflammatory cells, collagen, coagulation factors, antibodies, and scores of other proteins occurs at an accelerated rate during critical illness. Amino acids derived from muscle tissue or other somatic and visceral proteins become the building blocks for protein in healing tissue and host defenses. Thus, the site of a traumatic or surgical wound or an area of acute inflammation diverts protein from other body tissues. Proteins that would otherwise strengthen the diaphragm or myocardium or participate in host defense processes are less available, thus significantly compromising the patient. A large part of the goal of nutritional management is to provide sources of energy so that endogenous proteins are not required for energy (i.e., protein sparing) and to supply exogenous proteins so that all the needs of protein synthesis can be met without a breakdown of endogenous sources. Although oversimplified, a convenient number to remember for the basal protein requirement is 0.8 g/kg per day. The average critically ill surgical patients might require 1.5 g/kg per day, whereas patients with severe thermal

injury and head injuries might have requirements in excess of 2 g/kg per day.

Nitrogen Balance. Protein balance is most frequently determined through assessment of nitrogen balance. Nitrogen balance can be determined by measuring the amount of nitrogen excreted. This is most conveniently done by measuring the amount of urea excreted in the urine if one assumes that urea constitutes 85% of the total nitrogen excretion. Since each gram of nitrogen represents 6.25 g of protein, total protein intake can be compared with protein loss through an estimate of daily urea excretion. However, it is better to measure the total nitrogen in urine and other lost fluids because the percentage contained in urea can vary considerably.

Indirect assessments of protein reserves are based on the single measurement of body substances that are maintained at normal levels by rapid protein synthesis. A variety of visceral proteins that have relatively short half-lives have been assessed for their relationship to protein status. Prealbumin ($t_{1/2} = 2$ days), retinol-binding protein ($t_{1/2} = 10$ days), and transferrin ($t_{1/2} = 8$ days) have all been used in the evaluation of nitrogen balance. Albumin has limited utility given its relatively long half-life ($t_{1/2} = 21$ days). Some advocate insulinlike growth factor-1 as another short-lived serum visceral protein, with the major benefit being its relative independence of the inflammatory state of the patient. For example, prealbumin is a negative acute-phase reactant and serum levels will decrease in the presence of ongoing, acute inflammation. As a result, increasing levels of prealbumin might be consistent with the deposition of new protein or an abating inflammatory response, whereas a decrease might suggest a negative nitrogen balance or a new focus of inflammation or infection. For these reasons, these rapid-turnover visceral proteins should be used as only one measure of protein status.

Fat Metabolism

In a normal 80-kg man, about 1,000 cal are readily available as glycogen and other stored carbohydrates, 24,000 cal are available as protein, and approximately 140,000 cal are stored as fat. A 10,000-cal deficit accrued over 5 to 6 days of semistarvation in a critically ill patient is considered a severe, acute energy deficit. This seems paradoxical given the large amount of calories stored as fat. However, the problem of a 10,000-cal deficit is not the loss of a few kilograms of fat but rather the protein catabolism commonly associated with an energy deficit of this size.

With the exception of essential fatty acids, the critically ill patient has little need for the administration of exogenous lipid. If the entire nonprotein caloric requirement were administered solely as carbohydrate, glycemic control and CO_2 retention (or a need for a higher minute ventilation) would be the only potential adverse effects. Thus, lipid is provided to prevent essential fatty acid deficiency and minimally as a source of non-protein calories.

There is significant debate regarding the value of administering intravenous fat emulsions in patients requiring parenteral nutritional support. Selected studies report an increased risk of infection and other complications, including potential lung toxicity from released fatty acids, compared to patients not receiving lipid emulsions.⁵⁵ It is entirely possible that the improved outcomes in the patients not receiving lipids were related to the withholding of these fat infusions or due to the hypocaloric nutritional regimen (underfeeding) these patients received, which simplifies glycemic control along with all of its inherent benefits.

Vitamins and Minerals

A hypermetabolic patient catabolizes vitamins more rapidly than normal and can reach a deficiency state sooner. Additionally, the oxidative stress associated with reperfusion injury and

a systemic inflammatory response leads to depletion of endogenous antioxidants, including vitamins E and C. In this regard, there is evidence to suggest that high doses of vitamins E and C might improve outcome and lower the risk of multiple organ failure in critically ill surgical patients.⁵⁶ Adequate levels of other vitamins are readily available in commercially prepared formulations used for enteral or parenteral administration.

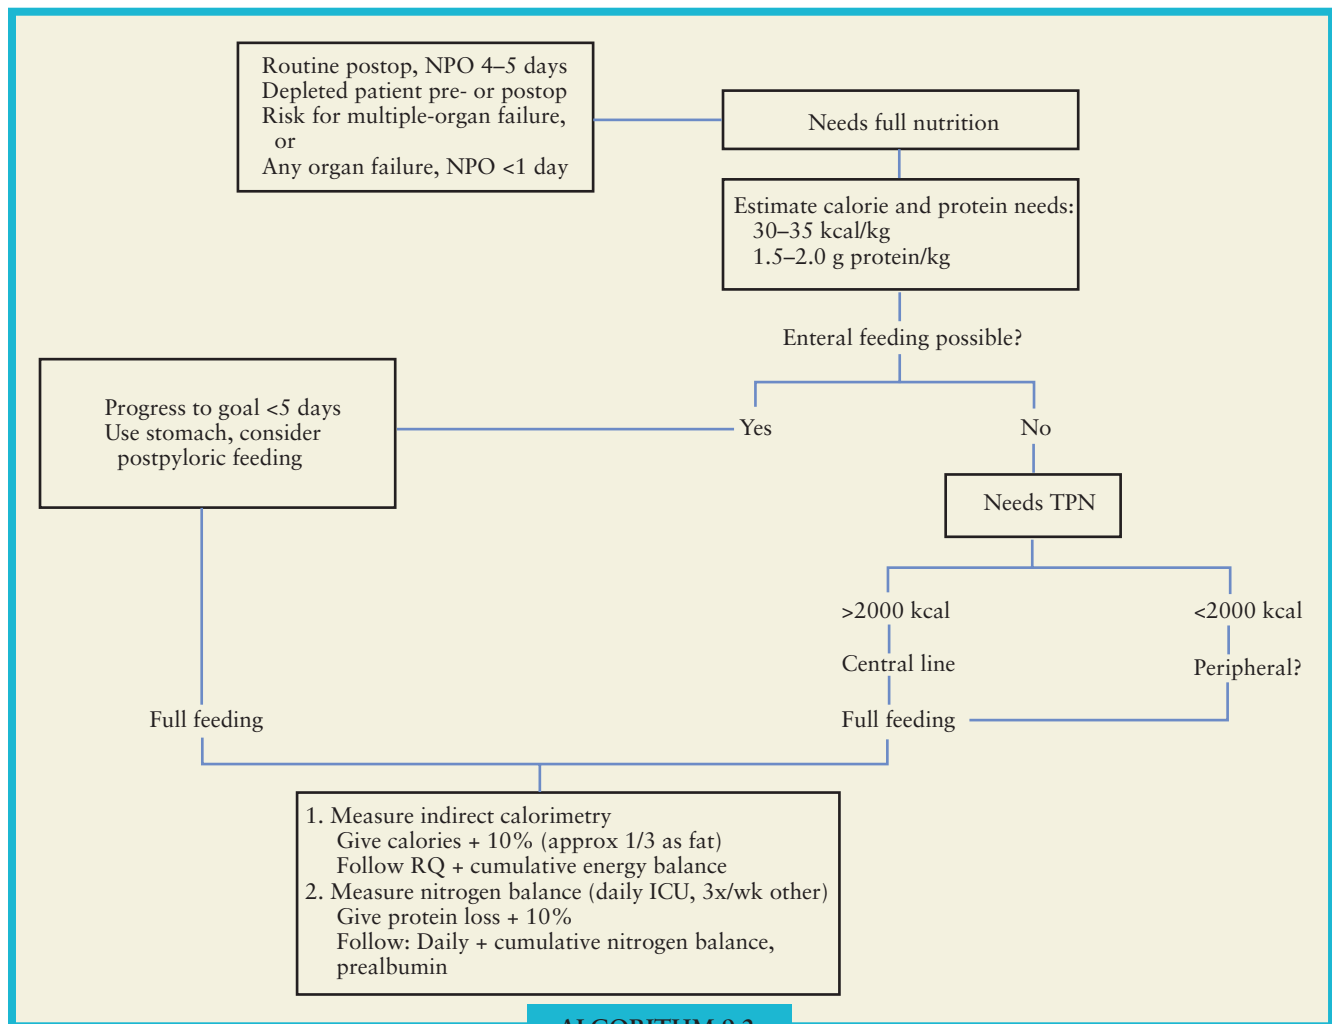

Mineral and trace metals must be managed more carefully than vitamins because a deficiency can occur more quickly and overdose can be deleterious. Calcium, phosphorus, and magnesium are lost continuously through the urine, stool, gastric juices, and other drainage. Although large body stores (particularly of calcium and phosphorus) are available, functional deficiency can develop rapidly. Enteral and parenteral feeding must include these elements and serum levels of calcium, phosphorus, and magnesium should be measured at regular intervals. In addition, zinc, copper, chromium, selenium, and manganese must be supplied to patients who are supported with enteral or parenteral feeding for more than 2 weeks.

Nutritional Support

- 6 Nutritional status should be assessed at the time of admission to the ICU with a view to determining whether the patient is mal-

nourished and the likelihood of timing to return to normal oral intake. Patients who are malnourished at the time of admission should receive nutritional support as soon as possible, typically once the acute resuscitation phase is over. In a systematic review of randomized controlled trials, early enteral nutrition (initiation within 36 hours of admission) was associated with a significantly lower risk of infections and a shorter hospital length of stay.⁵⁷ A reasonable goal for nutritional support is to meet the caloric and protein requirements within 5 days of ICU admission in adequately nourished patients in whom a return to oral intake is not imminent (Algorithm 9.2).

The critically ill patient is best provided energy and protein using the gastrointestinal tract whenever possible. This route has fewer risks of complications and is less costly than the parenteral route. Enteral feeding can be accomplished through a tube passed directly into the duodenum or jejunum at surgery or through a soft, small-bore feeding tube passed into the stomach through the nose or mouth. It is generally possible to accomplish tube feeding with gastric infusion and there appears to be no specific benefit to postpyloric enteral feeding with respect to rates of pneumonia due to aspiration.⁵⁸ However, in the case of intolerance, postpyloric feeding should be considered. Intolerance of gastric feeding usually manifests as large volumes (>300 mL) of residual feeds in the stomach on aspiration from the feeding tube. In this scenario, the feeding

ALGORITHM 9.2

ALGORITHM 9.2. Nutritional management. RQ, respiratory quotient; TPN, total parenteral nutrition. (Modified from Bartlett RH. *University of Michigan Critical Care Handbook*. Boston, MA: Little, Brown; 1996.)

tube should be advanced beyond the pylorus using endoscopy or fluoroscopy. Alternatively, prokinetic agents like metoclopramide or erythromycin may be effective.

Feedings should be given by continuous infusion rather than as large boluses. The patient should be positioned in a semirecumbent or sitting position (at a minimum of a 30-degree angle) to prevent regurgitation and aspiration and to lower the risk of ventilator-associated pneumonia. Gastric residuals should be checked if the patient feels uncomfortable or appears distended, but it is not necessary to check the residual more than once a day under most circumstances. With continuous tube feeding, a residual of 200 to 300 mL is normal.

It is better to start with a small amount of full-strength formula rather than a large amount of diluted formula. The rate can be advanced and gradually increased until the desired volume is reached. Hypernatremia can occur in patients who receive high-protein formulas or concentrated formulas or in those patients with significant free water losses. Hypernatremia should be managed by administering free water via the feeding tube. A serious problem with tube feeding is complete cessation of feedings because of diarrhea or a large gastric residual. If the tube feeding needs to be curtailed for any reason, it should be reinstituted the next hour at a smaller volume and gradually increased until the prescribed caloric load is reached.

Enteral Formulations. Commercially available formulas for enteral feeding generally contain 1 to 2 cal/mL and include 16% to 25% of calories as protein. Most of the calories are supplied as maltodextrins, hydrolyzed corn syrup, corn syrup solids, and sucrose. Those that are considered elemental, supplying amino acids rather than proteins, or are concentrated have a higher osmolarity and might cause cramps or diarrhea. If diarrhea occurs, other causes should also be considered such as antibiotic-associated diarrhea, pseudomembranous colitis, and sorbitol-containing medications.

Several specific substrates with immunologic effects have been added, alone or in combination, to a variety of enteral formulations. The number of these key nutrients, also called nutraceuticals or pharmacognutrients, continues to increase, but to date only arginine, glutamine, nucleotides, and omega-3 polyunsaturated fatty acids seem to play a role in the regulation of immunologic and inflammatory responses in critically ill patients. Several of the commercially available enteral preparations have some combination of these nutraceuticals, making it difficult to assess which alone or which combination offers optimal benefit while all are more costly. Several systematic reviews of randomized controlled trials indicate that these formulations appear to reduce the incidence of infectious complications, duration of mechanical ventilation, and length of ICU stay without any improvement in mortality.^{59,60} However, in the face of an ongoing excessive immunoinflammatory response, these agents may prolong the process and associated organ injury, such as ARDS.

Parenteral Nutrition. Commercial preparations for parenteral feeding are limited to glucose (20% to 70%) and fat (10% to 20%) as energy sources and amino acid or peptide solutions (5.5% to 15%) as protein sources. Total energy requirements should be met through administration of fat, carbohydrate, or both. Any protein administered should be available for anabolic processes. Parenteral feeding with carbohydrate is limited by the sclerotic effect of hyperosmolar solutions on veins. Effective parenteral feeding with carbohydrate alone requires solutions of at least 1 cal/mL (25% sugar). This type of solution must be administered into an area of rapid blood flow, generally the superior vena cava. Fat is a more efficient energy source and can be given through peripheral veins in concentrations of either 10% or 20%. The total daily energy requirement can be given as fat, or a major portion can be given as fat with the rest as carbohydrate. Both fat and carbohydrate are equally effective sources of energy. The ratio

between fat and carbohydrate energy sources and the ratio between total energy sources and grams of protein vary depending on the clinical state. For example, a patient with cardiac failure may require a solution that is low in volume and low in sodium but high in calories and protein. A patient with multiple intestinal fistulas may require large volumes, which allow for fewer calories and grams of protein per milliliter. As a rule of thumb, half of the calories can be provided by carbohydrate, 30% as fat, and the remainder as protein.

The standard solution can be modified for individual patients by raising or lowering the concentration of glucose and amino acids and by varying the electrolyte and trace metal composition. Vitamins and trace minerals are added to the solution at regular intervals. The standard solution must be supplemented with intravenous fat to provide at least 100 g of fat emulsion each week to preclude fatty acid deficiency. Fat emulsion may be administered through a peripheral vein or through a central catheter at the same time as the hypertonic glucose solution.

The most common complication of total parenteral nutrition is infection on or around the intravascular catheter. Of course, infection can occur with any indwelling vascular catheter, but it is more likely in the presence of hypertonic glucose and protein solutions. If catheter infection is suspected, the catheter must be removed and a new location and catheter placed. Hyperglycemia is also common and should be aggressively managed with an insulin infusion. A sudden increase in blood glucose levels in a patient receiving parenteral nutrition is often an early sign of infection. When this occurs, the patient should be thoroughly evaluated with this in mind.

STRICT GLYCEMIC CONTROL

The cytokine and hormonal milieu characteristic of critical illness leads to hyperglycemia such that virtually all patients have blood glucose levels in excess of 120 mg/dL. This response is due to a combination of increased peripheral insulin resistance and increased hepatic glucose production (Table 9.5). Hyperglycemia has several effects on immune function that potentially increase the risk of infectious complications. Specifically, elevated blood glucose levels increase proinflammatory cytokine production from monocytes; impair lymphocyte proliferation; decrease serum opsonic activity through glycosylation of immunoglobulins; and impair neutrophil chemotaxis, oxidative burst, adherence, and phagocytosis.

CLASSIFICATION OF ACUTE KIDNEY INJURY (RIFLE CLASSIFICATION)

■ RIFLE CATEGORY	■ GFR CRITERIA ^a	■ URINE OUTPUT CRITERIA	■ ICU MORTALITY
RISK	Increased serum creatinine $\times 1.5$ or decrease of GFR $>25\%$	Urine output <0.5 mL/kg/h for 6 h	5%
INJURY	Increased serum creatinine $\times 2$ or decrease of GFR $>50\%$	Urine output <0.5 mL/kg/h for 12 h	14.7
FAILURE	Increased serum creatinine $\times 3$ or decrease of GFR $>75\%$ or serum creatinine ≥ 4 mg/dL	Urine output <0.3 mL/kg/h for 12 h or anuria for 12 h	36.5
LOSS	Complete loss of renal function for >4 wk	47.6	
END-STAGE KIDNEY DISEASE	Need for renal replacement therapy for >3 mo		

^aEither GFR (glomerular filtration rate) or urine output criteria might be used to define the RIFLE classification.

Early evidence from randomized controlled trials suggested that strict glycemic control aiming for blood glucose in the range of 80 to 120 g/dL reduced mortality, principally due to a reduction in the risk of sepsis-induced organ failure.⁶¹ More recent trials and meta-analyses suggest that the relationship between glycemic control and mortality is more complex.^{62,63} It appears that there is no benefit and even a potential for harm in medical patients or mixed medical-surgical critical care units. By contrast, there appears to be a mortality benefit with a 40% lower risk of death in critically ill surgical and trauma patients.^{62,63} The differential effects are not easily explained and might relate to the attributable mortality of sepsis in medical as compared to surgical populations. What is evident from many of these trials is that the rate of hypoglycemic episodes is over fivefold greater (as high as 20% of all patients) and the nursing workload associated with titration of a continuous insulin infusion is significant. To mitigate some of these concerns, evidence-based guidelines suggest a tightly controlled insulin protocol and a more moderate approach, with a blood glucose target under 140 mg/dL.

ACUTE RENAL FAILURE

Acute renal failure (ARF) complicates approximately 5% of ICU admissions. By definition, ARF is an abrupt decrease in kidney function that results in the accumulation of nitrogenous solutes. ARF may be oliguric (urine output <400 mL/d) or nonoliguric (urine output is normal or increased while solute clearance is markedly decreased). It is now recognized that renal dysfunction occurs along a continuum, such that the term more appropriately used in the ICU is *acute kidney injury* (AKI), which is graded using the RIFLE (*risk, injury, failure, loss, end-stage kidney disease*) classification (Table 9.6).^{64,65} The mortality of ARF in the surgical ICU is high (50% to 90%) because ARF is usually just one component of severe multiple organ failure. The mortality from nonoliguric ARF is significantly less than that from oliguric ARF, although many patients progress to oliguria with its poor outcome. Regardless of urine output, the sequelae of ARF result from the retention of metabolic wastes indicated by a progressive rise in blood urea nitrogen (BUN) and serum creatinine concentrations. Hypervolemia and electrolyte imbalances further complicate the management of oliguric ARF.

Etiology of Acute Renal Failure

The pathogenesis of ARF is commonly classified as prerenal, postrenal, or intrinsic parenchymal disease (renal). In any

patient with renal dysfunction, prerenal and postrenal (obstructive uropathy) causes should be excluded (Table 9.7). Obstructive etiologies can easily be excluded using ultrasonography to evaluate the kidneys, ureters, and bladder. Parenchymal disease is the most frequent cause of ARF in the ICU, with acute tubular necrosis (ATN) being the most common pathologic finding.

ATN is the death of tubular cells, which occurs due to either ischemia (ischemic ATN) or nephrotoxic agents (toxic ATN). Ischemic ATN is seen in the context of sepsis, hypovolemia, major surgery (likely related to changes in intravascular volume), or cardiogenic shock. Under conditions of diminishing renal blood flow, perfusion of the kidneys is first maintained by vasomotor responses, which dilate the afferent arteriole and constrict the efferent arteriole. As continued hypotension is detected by the juxtaglomerular apparatus, the renin-angiotensin system is activated in concert with the sympathetic release of other vasoactive hormones. These substances produce vasoconstriction systemically, including the afferent arteriole, and further exacerbate cortical hypoperfusion. Casts of cellular debris obstruct the lumen, and cellular edema occurs. As tubular cells become necrotic and slough off, the leakage of glomerular ultrafiltrate back across the proximal tubular membrane into the interstitium causes edema. Acute tubular necrosis consists of a spectrum of effects of cortical ischemia, ranging from polyuria with tubular dysfunction to temporary anuria to renal cortical necrosis with chronic anuria.

TABLE 9.7

STANDARD MEASUREMENTS IN THE DIAGNOSIS OF RENAL FAILURE

■ TEST	■ PRERENAL	■ PARENCHYMAL
Urine osmolality (mOsm)	>500	250–350
U/P osmolality	>1.5	<1.1
U/P creatinine	>20	<10
Urine sodium	<20	>40
FE _{Na}	$<1\%$	$>3\%$

FE_{Na}, fraction of excreted sodium; U/P, urine-to-plasma ratio.

Toxic Acute Tubular Necrosis

Toxic ATN might occur as a result of pigments (myoglobin, hemoglobin), radiocontrast media, or drugs. Pigment nephropathy due to the effects of myoglobin following trauma, major burns, global ischemia, or operation is not uncommon in the surgical intensive care unit. Rarely, hemoglobinemia due to massive intravascular hemolysis might also give rise to pigment nephropathy. ARF due to circulating myoglobin occurs in almost half of patients with significant rhabdomyolysis. Rhabdomyolysis leads to ATN through three mechanisms: intrarenal vasoconstriction and ischemia, cast formation with tubular obstruction, and the direct toxic effects of myoglobin on the renal tubules. Although myoglobin is not a direct nephrotoxin, in the presence of aciduria, myoglobin is converted to ferrihemate, which is toxic to renal cells. Rhabdomyolysis should be suspected in patients with burns, trauma, seizures, alcohol or drug intoxication, prolonged ischemia in muscle groups, and extended coma.

The presence of myoglobin in the urine can be first suspected by the presence of dark, tea-colored urine and then confirmed with a positive urine dipstick, which reacts with the heme groups of both myoglobin and Hgb. The absence of red cells on microscopy confirms that the discolored urine is caused by myoglobin. High serum levels of creatinine phosphokinase (CPK) or myoglobin, in combination with evidence of urine myoglobin, confirm the diagnosis. One characteristic feature of early rhabdomyolysis-induced acute kidney injury that differs from other forms of ATN is the presence of a low fractional excretion of sodium ($<1\%$), a potential manifestation of the importance of vasoconstriction and tubular occlusion in its pathogenesis.⁶⁶

Patients with either CPK greater than 20,000 IU/L or serum myoglobin greater than 10,000 ng/mL are at highest risk for pigment nephropathy. Measures should be instituted to prevent pigment nephropathy and lower the likelihood of requiring renal replacement therapy (RRT). The most important measure is volume expansion with or without administration of diuretics to achieve a urine output of 150 to 200 mL/h. Mannitol is an ideal diuretic in this sense as it induces an osmotic diuresis and as an oxidant scavenger might reduce iron-mediated oxidative injury to the renal tubules. Many intensivists also attempt to alkalinize the urine ($\text{pH} \geq 7$) through the administration of sodium bicarbonate solutions, although evidence supporting this approach is lacking. Forced diuresis should continue until the urine is clear of myoglobin.

Radiocontrast media is another frequent cause of toxic ATN in surgical patients and is the third most common cause of ARF in hospitalized patients. It is believed to be due to both renal vasoconstriction leading to medullary ischemia and oxidant injury. The incidence of contrast nephropathy is about 1% to 3% when defined as a 25% elevation in serum creatinine. Risk factors include mode of administration (intraarterial $>$ intravenous), advanced age, preexisting renal dysfunction, diabetes, hypovolemia, nonsteroidal anti-inflammatory drug (NSAID) use, and type of radiocontrast agent.⁶⁷

Contrast nephropathy is usually experienced as an asymptomatic, transient rise in creatinine but may progress to oliguric renal failure that requires hemodialysis (HD). Volume expansion with saline is probably the most effective means of preventing contrast nephropathy in high-risk patients. There are conflicting reports regarding the effectiveness of N-acetylcysteine and sodium bicarbonate in preventing acute kidney injury following radiocontrast media exposure. N-acetylcysteine may protect against the effects of free radicals, while sodium bicarbonate is believed to prevent their formation. Taken together, the evidence suggests that at a minimum, either of these adjunctive measures is not harmful and might be beneficial.⁶⁸

Management of Acute Renal Failure

In surgical patients, ARF rarely occurs in isolation. Rather, ARF is only one component of a syndrome of multiple organ failure that is often accompanied by infection. The treatment of these patients, therefore, should be focused on managing the underlying disease processes. The development of ARF complicates the care of surgical patients by introducing difficulties in fluid, electrolyte, and nutritional management. The adverse effects of RRT further compound these problems. A favorable outcome can be achieved only through aggressive intervention. This includes surgical drainage of infectious foci, excision of necrotic tissue, early implementation of effective RRT, and full nutritional support (Algorithm 9.3).

General Care

With nonoliguric ARF, the treatment may differ little from that required for identical patients with normal renal function. The management of fluids, solutes, and nutrition is usually unaffected by nonoliguric ARF, although the BUN may be elevated. The extent of renal dysfunction is limited and almost always reversible. The use of renal replacement therapies (and their inherent complications) is rarely necessary.

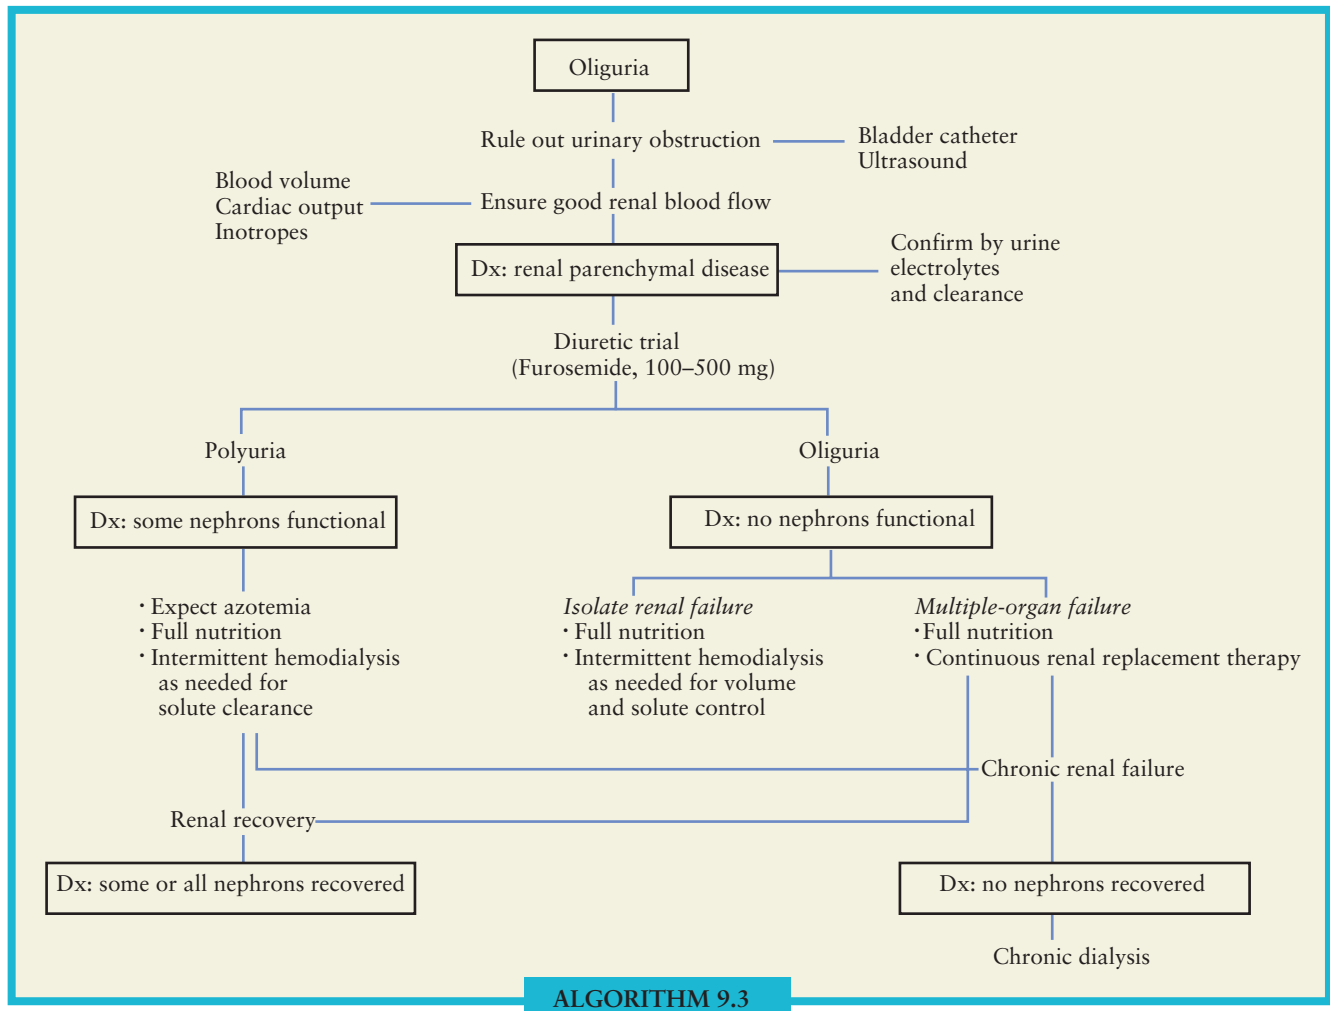

Oliguria and anuria pose several management difficulties. In the absence of normal urine output, problems of fluid overload can lead to anasarca, pulmonary edema, and congestive heart failure. The pharmacokinetics of drugs becomes difficult to predict as a result of decreased elimination and increased volume of distribution. In light of these risks, the volume status of patients with ARF must be carefully monitored. Fluid intake and output must be precisely tabulated, and the body weight should be measured daily. Pulmonary artery catheterization may be necessary to monitor the fluid status of these patients more closely. Treatment options for hypervolemia consist of fluid restriction or fluid removal with some form of RRT. Fluid restriction, however, limits the administration of intravenous medications and may preclude adequate nutrition.

ARF can create severe derangements in electrolyte and acid-base physiology. Serum electrolytes should be measured at least daily. Of all the electrolyte abnormalities that can occur with ARF, hyperkalemia is the most serious. Under the conditions of hypercatabolism and tissue necrosis that characterize these patients, large amounts of potassium may be generated and accumulate during a short period of time. Acute hyperkalemia causes a decrease in cardiac excitability, which can ultimately result in asystole. The removal of potassium must be accomplished with RRT or ion exchange resins. Other electrolyte abnormalities, such as hyponatremia, hyperphosphatemia, hypocalcemia, and metabolic acidosis, are common in ARF and must be monitored closely. Treatment consists of appropriate additions or restrictions of intravenous solutions and effective use of RRT.

Platelet dysfunction and coagulopathy are often associated with ARF. A reproducible platelet defect can be demonstrated experimentally with a BUN of 100 mg/dL. This defect can be transiently reversed with administration of desmopressin (DDAVP). Platelet transfusion in this clinical setting will be ineffective because the transfused platelets will rapidly acquire the same dysfunction at the patient's platelets. Anemia also accompanies ARF in surgical patients. In addition to the loss of blood during hemorrhage or operation, the production of erythropoietin has been shown to decrease in direct proportion to the decrease in renal function.

Nutritional Support in Acute Renal Failure

The goal of nutritional support in ARF is to provide optimal amounts of calorie and protein substrates to minimize

ALGORITHM 9.3. Management of acute renal failure. CAVH, continuous arteriovenous hemofiltration; CAVHD, continuous arteriovenous hemodialysis; PD, peritoneal dialysis.

autocatabolism and allow tissue anabolism, wound healing, and sustained immune function. In any discussion of nutrition and renal failure, it is necessary to point out the distinction between acute and chronic renal failure. Patients with chronic renal failure are generally healthy, and their energy requirements differ little from those of persons without chronic renal failure. Protein intake is required only for metabolic turnover and is restricted to minimize the generation of urea and other products of protein metabolism.

By contrast, the metabolic requirements of a patient with ARF are those of a critically ill, hospitalized patient. Actual measurement of resting energy expenditure has shown that the caloric requirements of patients with multiple organ failure and ARF are often 50% above those of normal, healthy subjects. Measured protein requirements may be increased to as much as 2.5 g/kg to provide for anabolic wound healing and sustained immune function. For these patients, protein restriction is counterproductive and potentially detrimental. Urea generation is best minimized by providing enough energy substrates (carbohydrates and lipids) to prevent the cannibalization of endogenous protein as an energy source.

A positive energy balance may also make the management of uremia and hyperkalemia less difficult. When a patient receives fewer calories than those expended, the difference must be made up from endogenous stores. In a well-nourished person, carbohydrate stores rarely exceed 2,500 kcal. After these stores have been depleted, lipid and protein stores are

mobilized. In the diseased state, endogenous protein has been shown to be catabolized preferentially as an energy substrate in the absence of readily available glucose. With the catabolism of protein, urea is generated. In addition, catabolic wasting of tissues and cells liberates excess potassium. Maintaining a positive energy balance with glucose and lipids should reduce protein catabolism, urea generation, and hyperkalemia.

Renal Replacement Therapy

Indications for the use of RRT include fluid overload (pulmonary edema, congestive heart failure), hyperkalemia, metabolic acidosis, uremic encephalopathy, coagulopathy, and acute poisoning⁶⁹ (Table 9.8). The optimal timing of initiation of therapy has not been definitively established, but it is preferable to begin renal replacement before complications occur. In the only randomized controlled trial to date, there was no improvement in mortality or renal recovery in patients in whom RRT was initiated within 12 hours of developing ARF compared to initiation once conventional indications for dialysis were met.⁷⁰

The three modalities of RRT frequently used in the critical care setting include intermittent HD, continuous RRT, and a recently introduced hybrid modality referred to as sustained low-efficiency dialysis (SLED).⁷¹

TABLE 9.8**PROPOSED CRITERIA FOR INITIATION OF RENAL REPLACEMENT THERAPY IN CRITICALLY ILL PATIENTS WITH ACUTE RENAL FAILURE**

Pulmonary edema
Unable to meet nutritional requirements due to volume load (pulmonary edema)
Oliguria: urine output <200 mL in 12 h
Anuria: urine output <50 mL in 12 h
Hyperkalemia: potassium concentration >6.5 mmol/L
Severe acidemia: pH <7.0
Azotemia: urea concentration >30 mmol/L
Uremic encephalopathy
Uremic neuropathy/myopathy
Uremic pericarditis
Plasma sodium abnormalities: concentration >155 mmol/L or <120 mmol/L
Hyperthermia
Drug overdose with dialyzable toxin

Adapted from Lameire N, Van Biesen W, Vanholder R. Acute renal failure. *Lancet* 2005;365:417–430.

Intermittent Hemodialysis. In intermittent HD, blood is circulated through a porous, hollow-fiber membrane that is permeable to solutes of less than 2,000 D. An isotonic solution surrounding the membrane provides a concentration gradient for the selective removal of solutes such as potassium, urea, and creatinine, whereas plasma concentrations of sodium, chloride, and bicarbonate are unchanged. A roller pump is used to maintain an extracorporeal blood flow of about 300 mL/min through an arteriovenous shunt or a double-lumen venovenous access. The transmembrane pressure gradient created by the pump affects the desired amount of fluid removal. Full systemic anticoagulation is required for this procedure, although less heparin may be used in patients with a baseline coagulopathy. Solute and volume removal with HD is considered very efficient relative to removal with the other methods of renal replacement. This efficiency is reflected in the clearance of water-soluble drugs such as aminoglycosides, cephalosporins, and penicillins. Plasma concentrations may be decreased by as much as 50% per treatment; accordingly, these drugs should be administered after treatments with close monitoring of serum concentrations. HD is also the method of choice for the rapid removal of life-threatening toxins and poisons.

Although the incidence of complications of HD is insignificant in the treatment of patients with chronic renal failure, frequent and often profound complications may occur when it is used to treat critically ill patients with ARF. In the acute setting, HD has been shown to cause hypotension, hypoxemia, and hemolysis and to precipitate cardiac arrhythmia. These events limit the application of HD in patients who are hemodynamically unstable.

Continuous Renal Replacement Therapy. Continuous renal replacement techniques offer the advantage of improved hemodynamic stability with continuous clearance of toxic metabolites and fluid removal. Continuous venovenohemodialysis (CVVHD) is the most commonly used method in the ICU. In this technique, venous access is obtained by means of a temporary double-lumen central venous dialysis catheter, which is

placed percutaneously in the subclavian, internal jugular, or femoral vein. Blood is pumped by a peristaltic pump through a filter against the flow of dialysate, which is pumped into the non-blood portion of the filter in the opposite direction. Rates of fluid removal are adjusted as necessary to maintain hemodynamic stability while the concentrations of solutes in the dialysate are adjusted to ensure adequate clearance of potassium, acid, and other products of uremia. Continuous RRT allows for slow but continuous removal of fluid and clearance of toxic wastes. Compared with intermittent HD, continuous RRT provides better hemodynamic stability, maintenance of cerebral perfusion, and control of fluid balance. It is therefore indicated in patients with renal failure and critical illness and may be the treatment of choice for ARF in this patient population.

The high costs related to specialized machinery, filters and lines, and filtrate replacement fluid might be prohibitive for some centers. This factor, combined with the frequent interruptions of continuous RRT due to the need for diagnostic and therapeutic procedures, and the increased workload for already overtaxed ICU nurses, renders CVVHD problematic. To mitigate these challenges, several centers have advocated the use of SLED, which uses standard intermittent hemodialysis equipment but aims for lower solute clearance over a prolonged period of time (e.g., 8 to 12 hours/session). In early studies, patients unable to tolerate conventional intermittent HD due to hypotension maintained hemodynamic stability using this hybrid approach.⁷¹

Meta-analyses of several randomized controlled trials suggest that there is no benefit to one modality over another in terms of renal recovery or mortality; thus, the choice should be dependent on local resource availability and patient-specific factors (Table 9.9).⁷² While earlier studies suggested that “higher dose” dialysis as a reflection of the frequency (or intensity) of dialysis offered benefit, more recent studies suggest there is no relationship between the dose of dialysis and renal recovery or mortality; thus, the frequency and intensity should be tailored to patient need.⁷³

Prognosis in Acute Renal Failure

The survival of patients with ARF depends on the successful treatment of the primary disease causing renal failure. The anephric patient supported with RRT survives until disease of some other organ system supervenes. The mortality among patients with multiple organ failure dependent on RRT ranges from 50% to 90%.

For patients who survive the acute phase of illness, the recovery of renal function after ARF depends on the type and extent of injury to the renal parenchyma. RRT may be required for several weeks until urine output and solute excretion return to acceptable levels. If renal function has not returned after 6 weeks, recovery is unlikely, and provisions should be made for long-term renal substitution therapy. In most studies, approximately 70% of survivors will require long-term renal replacement.

PROGNOSTICATION AND INTENSIVE CARE UNIT OUTCOME

- 8 The critical care environment is filled with an abundance of data. Data are collected at the time of admission and almost daily, allowing repeated assessment of physiologic status over time. This data-rich environment has led to the development of scoring systems that provide information regarding the likelihood of survival based on information available early during the course of the ICU stay. Many systems that have been developed focus not on prognosticating survival but rather on the

TABLE 9.9**ADVANTAGES OF INTERMITTENT HEMODIALYSIS AND CONTINUOUS RENAL REPLACEMENT THERAPY**

■ INTERMITTENT HEMODIALYSIS	■ CONTINUOUS RENAL REPLACEMENT THERAPY
Advantages Lower risk of systemic bleeding Facilitates transport for other interventions More suitable for severe hyperkalemia Lower cost	Better hemodynamic stability Fewer cardiac arrhythmias Improved nutritional support Better pulmonary gas exchange Better fluid control
Disadvantages Availability of dialysis staff More difficult hemodynamic control Inadequate dialysis dose (frequency) Inadequate fluid control Inadequate nutritional support Not suitable for patients with intracranial hypertension No removal of cytokines (theoretical) Potential complement activation by nonbiocompatible membranes	Greater vascular access problems Higher risk of systemic bleeding Long-term immobilization of patient More filter problems (rupture, clotting) Greater cost

assessment of potential outcome, typically in the degree of organ dysfunction. The differences in these two approaches are highlighted in Table 9.10.

Prognostic Scoring Systems

Prognostic scores were developed to maximize their predictive capacity. The APACHE, the simplified acute physiology score (SAPS II), and the mortality prediction model (MPM) systems constitute the three most widely used prognostic models.^{74–76}

Each model assumes that mortality will be influenced by extreme physiologic derangement that occurs early in the course of the illness and before optimal resuscitation. Each uses data that are available early in the ICU admission to construct a composite severity of illness measure.

The most frequently utilized prognostic score is the APACHE II system, consisting of data derived from 12 physiologic variables, age, and chronic health status, yielding a score of 0 to 71. Major limitations of this system include the fact that risk predictions are based on outcomes of treatment from 1979 to 1982; the system was not designed to predict

TABLE 9.10**SCORING SYSTEMS IN THE ICU**

	■ PROGNOSTIC SCALES: SEVERITY OF ILLNESS	■ OUTCOME MEASURES: ORGAN DYSFUNCTION SCALES
Uses	Prognostication; risk stratification	Outcome prediction; evaluation of clinical course over time
Timing of ascertainment	Early during ICU stay	Following resuscitation; at any time during ICU stay
Selection of variables	Physiologic measures Worst values Selected to maximize predictive capacity	Measures of physiology or therapeutic response Stable, representative values Selected to reflect clinical construct
Calibration	Maximize prediction	Maximize description

ICU, intensive care unit.

TABLE 9.11**ORGAN DYSFUNCTION SCORING: THE MARSHALL MULTIPLE ORGAN DYSFUNCTION SCORE**

■ ORGAN SYSTEM	■ 0	■ 1	■ 2	■ 3	■ 4
Respiratory (PaO ₂ /FiO ₂)	>300	226–300	151–225	76–150	≤75
Renal (serum creatinine, mg/dL)	≤1.1	1.2–2.3	2.4–3.9	4.0–5.6	>5.7
Hepatic (serum bilirubin, mg/dL)	≤1.1	1.2–3.5	3.6–7.1	7.2–14.1	>14.2
Cardiovascular (PAR ^a)	≤10.0	10.1–15.0	15.1–20.0	20.1–30.0	>30.0
Hematologic (platelet count × 10 ⁻³)	>120	81–120	51–80	21–50	≤20
Neurologic (Glasgow Coma Scale score)	15	13–14	10–12	7–9	≤6

outcome for individual patients; and there is lead time bias—unless all admissions were entered at the same time in the course of the patient's illness, there will be errors in prediction. APACHE III is a more recent model and is derived from information on 17 variables.⁷⁷ APACHE III is proprietary and has not been widely adopted.

SAPS II is composed of 17 variables, which include 12 physiologic variables, age, type of admission (medical, surgical, scheduled surgical, unscheduled surgical), and variables that are related to specific underlying diseases. The MPM is less based on physiology than APACHE II or SAPS and was designed to measure mortality risk at 24 and 48 hours after ICU admission. This longer time interval provides a revised risk based on patient response to resuscitation and early treatment. There are minor differences across these prognostic measures in terms of their predictive capacity, but there are no data to support that one offers significant improvement over another. Pertinent to the discussion on futility, these severity of illness systems provide only estimates of mortality. For example, a mortality estimate of 75% means that approximately 75 of 100 patients with this probability would be expected to die, but it is not possible to ascertain whether any specific, individual patient will be 1 of the 75 patients that dies or 1 of the 25 that lives.

Outcome Measures

Organ failure is a relatively frequent occurrence in critically ill patients and has resulted in attempts to describe and quantify organ dysfunction. This is a difficult process because organ failure is dynamic and represents a broad spectrum of disease. Which organ systems to include and which measures one should use to quantitate organ dysfunction remain controversial. Most scores focus on six organ systems: respiratory, cardiovascular, hematologic, central nervous system, renal, and hepatic. These outcome measures have conceptual appeal for several reasons. First, they provide an estimate of baseline severity for entry into clinical trials, whereas serial evaluation might provide information on mortality risk. With these organ dysfunction measures, the burden of disease experienced by the patient throughout the course of ICU stay is captured. By contrast, with prognostic scoring systems there is but an early snapshot of the patient's physiologic status, whereas information regarding the remainder of the patient's course is lost.

The most commonly used outcome measures include the Sequential Organ Failure Assessment (SOFA) Score and the Multiple Organ Dysfunction (MOD) Score or Marshall Score, both of which capture data on the six aforementioned sys-

tems^{78,79} (Table 9.11). A Marshall score of greater than or equal to 4 (≥6 in select studies) is used to indicate MOD. By contrast, posttraumatic multiple organ failure is often assessed using a discrete scoring system limited to only four organ systems (also known as the Denver Score).⁸⁰ Hematologic dysfunction and neurologic dysfunction are not captured, likely due to the frequency of coagulopathy and traumatic brain injury, which relate to the initial injury rather than the development of organ dysfunction. A Denver Score of greater than or equal to 4 is indicative of MOD. Like the prognostic scoring systems, no single measure of organ dysfunction is superior or predictive in the individual patient.

ETHICS IN THE INTENSIVE CARE UNIT

The availability of advanced technologies to prolong life in the ICU has resulted in a number of controversies centered on their appropriate use. The controversies have developed under the guise of the technologic imperative, implying that the availability of technology requires that this technology be used. To counter the technologic imperative, physicians have often invoked the concept of futility to limit its inappropriate use, resulting in confusion and, at times, conflict when caring for critically ill patients.

In the strictest sense, true medical futility occurs rarely and signifies interventions that simply should not be offered. For example, we do not offer ongoing medical care to a patient who meets criteria for brain death. The majority of interventions that physicians judge to be futile are not truly futile. They should more accurately be considered inadvisable or inappropriate because the chances of achieving the intended goal are exceedingly low, their benefits are controversial, or their costs are excessively great. Implicit in this definition is a clear understanding of the real or perceived therapeutic endpoint; that is, it is meaningless to say an intervention is futile without specifying the goal of the intended therapy. Conflicts arise when there are disagreements about the intended goal, whether the desired goal is appropriate, and whether the probability of success is sufficiently great. In this sense, there are both qualitative (value-driven) and quantitative (probabilistic) aspects to the understanding and application of futility in the ICU.

Quantitative futility describes a clinical situation in which the application of an intervention has a very low probability of producing a satisfactory outcome—usually survival. There have been a large number of prognostic scoring systems developed to compare outcomes in large groups of patients.

Although these scoring systems were not devised to predict outcome in individual patients, there has been some effort on the part of physicians to adapt these measures for this purpose. In effect, if the probability of survival is below a certain threshold, the intervention might be considered futile or inadvisable and not instituted. Physicians are not very capable at assigning an estimated probability of outcome for an individual patient. Further, this threshold varies across physicians and patients, making decisions based on quantitative futility difficult.

Qualitative futility describes the clinical situation in which the outcome is survival but with an unsatisfactory quality of life. Excellent examples of qualitative futility include patients in a persistent vegetative state or patients dependent on intensive medical care. Conflict arises when what is defined as unsatisfactory for one party might be acceptable for the other. For example, the family of a critically ill, severely debilitated elderly stroke patient might consider the maintenance of life of greatest importance, whereas the physicians believe that given the expected quality of life, further care would be futile.

Inappropriate declarations of futility are common; we rarely can predict with absolute certainty whether a patient will survive his or her ICU stay. In effect, we offer opinions colored by our own values, not objective data. The tendencies to frame value judgments as medical decisions based on such data are inappropriate. Therapeutic interventions should be directed not toward eliciting a desired physiologic effect but toward an agreed-on goal that is consistent with the wishes of the patient while maintaining professional integrity. Failure to reach the prespecified goal renders the treatment futile. In one study of patients with an expected probability of death of greater than 95%, only 20% of patients had advance directives to guide care, leading to a lack of clarity of what the intended goal might be.⁸¹ Further, 15% of families had unrealistic expectations regarding survival. In this latter group, rates of resource utilization (transfusion, advanced imaging modalities, dialysis, surgery) were significantly greater than patients whose families did not have unrealistic expectations. These data suggest that the families influenced the caregivers to use resources more extensively than would have been the case otherwise. In situations such as these, intensivists should consider the use of ethics consultations when the goals cannot be agreed on or when confusion exists. Consultation with an ethicist is not to decide the answer but to receive input from an impartial individual who often brings a fresh approach to a difficult situation. In one randomized controlled trial, the use of ethics consultations shortened the duration of ICU stay and reduced the use of life-sustaining treatments without altering overall mortality.⁸² In this study, the majority of physicians, nurses, and patients/surrogates agreed that ethics consultations in the ICU were helpful in addressing treatment conflicts.

CHAPTER 10 ■ FLUIDS, ELECTROLYTES, AND ACID-BASE BALANCE

RICHARD B. WAIT AND REGINALD ALOUIDOR

KEY POINTS

- 1 The human body is conceptualized as composed of at least four compartments: water, protein, fat, and bone ash.
- 2 Sodium (extracellular fluid [ECF]) and potassium (intracellular fluid [ICF]) are the dominant cations and, whereas composition varies between ECF and ICF, overall concentration of solutes in these fluids is identical.
- 3 Osmolality is kept constant by tight regulation of water balance by osmoreceptor-induced control of antidiuretic hormone and thirst.
- 4 Effective circulating volume is sensed by volume receptors (capacitance vessels, atria, hepatic, and central nervous system) and pressure receptors (aortic arch, carotid, and intrarenal) that alter sodium and water balance mediated by renin-angiotensin, aldosterone, atrial natriuretic peptide, dopamine, and renal prostaglandins.
- 5 Water losses involve both sensible (measurable) via urine, stool, and sweat and insensible (unmeasurable) via evaporative loss from both the skin and respiratory tract.
- 6 Goals of fluid therapy are to normalize hemodynamic parameters and body fluid electrolyte concentrations and can be achieved with crystalloids (preferable) or colloids, both correcting deficits and matching ongoing or expected losses.
- 7 The major cations (Na^+ , K^+ , Ca^{2+} , and Mg^{2+}) should be monitored and replaced, recognizing unique distributions and impact of various diseases.
- 8 Acid-base balance is carefully buffered within very narrow limits. Acid-base disturbance and compensation are frequently mixed, involving respiratory and metabolic-renal responses.

A thorough understanding of fluid and electrolyte composition and management is essential to the effective care of surgical and critically ill patients. Disease- and injury-related alterations in fluid volume and electrolyte physiology are complex and cannot be fully understood without first understanding normal physiologic mechanisms of fluid and electrolyte homeostasis, inclusive of acid-base balance considerations. In this chapter, these mechanisms are reviewed and used as a starting point for presentation of fluid and electrolyte pathophysiology and management of specific clinical situations.

BODY FLUIDS

Total Body Water and Body Fluid Compartments

Traditionally, most scientists used a two-compartment model of tissues within the body: the fat compartment and the fat-free or lean tissue compartment. Over the past 20 years, technology has added significantly to our knowledge of body composition, and more complex models have been developed, the simplest of which is the four-compartment model. In this model, the fat-free mass is actually composed of three separate compartments: water, protein, and bone ash. The remaining compartment is fat, which is considered to be triglycerides, because adipose tissue, a more general descriptor, also contains small amounts of water. *Total body water* (TBW) is defined as the total volume of water within the body. TBW has traditionally been measured using indicator dilution techniques in which radioactive tracers such as deuterium oxide (D_2O) were given to subjects and a steady state allowed to develop before measurements of the D_2O in the plasma were made. More recently, other techniques have added greatly to our ability to measure TBW content as well as the content of

all of the elements within the body such as *neutron activation analysis*, in which the body is exposed to a source of thermal neutrons. These neutrons enter the atomic nuclei, resulting in the transformation of that nucleus to a more activated energy state. This activated state is transient and later returns to the baseline, resulting in energy release from the nucleus in the form of gamma radiation, which can then be measured using whole-body shielded gamma detectors.¹ In recent years multi-component models of body composition based on dual-energy x-ray absorptiometry (DEXA), computed tomography (CT) scan, and magnetic resonance imaging (MRI) have been developed in order to provide estimates of the various components of the fat-free mass as well as the distribution of the adipose organ. These techniques can be useful when it is expected that the fat-free mass is altered and that the simple two-component model cannot be applied.² Using these techniques, total body oxygen, carbon, hydrogen, nitrogen, calcium, phosphorus, sulfur, potassium, sodium, and chlorine can be measured. These measurements, in turn, can be used to calculate steady-state body composition using standard formulas. For example, total body protein can be calculated as total body nitrogen \times 0.625, because 99% of the body's nitrogen is found within protein. More complex mathematical models are needed when calculating the composition of components using elements that are distributed among more than one component of the body (e.g., TBW and fat).

The relationship between TBW and body weight varies according to percentage of body fat. Differences in percent TBW between individuals can generally be accounted for by differences in relative body fat content. Average TBW is 60% of body weight in adult men and 50% in adult women. In infants, water makes up approximately 80% of body weight. This figure decreases to approximately 65% by 1 year of age and continues to decrease slowly throughout life, primarily related to decreases in lean body mass. Estimates of TBW can be empirically adjusted for the obese and thin body habitus. In

TABLE 10.1

BODY FLUID COMPARTMENTS

	■ BODY WEIGHT (%)	■ TOTAL BODY WATER (%)
Total	60	100
Intracellular	40	67
Extracellular	20	33
Intravascular	5	8
Interstitial	15	25
Transcellular	2	4

obesity, estimates of TBW can be decreased by 10% to 20%. In very thin individuals, estimates can be increased by up to 10%.

TBW is distributed into specific compartments in dynamic equilibrium with one another. The principal of these are the intracellular and extracellular compartments (Table 10.1). Intracellular fluid (ICF) makes up approximately two thirds of the TBW, and the remaining one third is composed of extracellular fluid (ECF). The ECF compartment has traditionally been measured using *inulin*, which distributes itself primarily within the ECF. More recently, ECF estimates have been made by measuring the volume of distribution of either bromide or sulfate isotopes, both of which are distributed primarily within the ECF. Using these techniques, ECF volume estimates range from 30% to 33% of TBW, or approximately 20% of body weight.

ICF cannot be measured directly, however, because the majority of potassium within the body resides within the intracellular space; measurements of total body potassium (TBK) can be used to estimate intracellular water. This is accomplished using a technique similar to neutron activation analysis. Normally, potassium within the body exists in two states, non-radioactive ^{39}K and radioactive ^{40}K . Because ^{40}K represents a stable proportion of total K within the body (0.0118%), measurement of the gamma radiation of the ^{40}K radioisotope using the sensing equipment similar to that used in neutron activation analysis can be accomplished. The TBK can then be calculated as $\text{TBK (mmol)} = ^{40}\text{K}/0.000118$.³ If one knows the size of

the ECF compartment and multiplies this by the known quantity of ^{40}K measured in a serum sample, the ICF can then be calculated by subtracting this total from the TBK.

The ECF compartment is subdivided into the intravascular and interstitial spaces. The intravascular space accounts for 25% of the ECF and contains the plasma volume, which is approximately 8% of the TBW or 5% of body weight. Interstitial water volume is calculated as ECF–intravascular space volume and constitutes approximately 25% of TBW, or 15% of body weight. The interstitial space extends from the blood vessels to the cells themselves and includes the complex ground substance making up the acellular tissue matrix. The water in this space exists in free and bound phases. The free phase contains water that is freely exchangeable with intravascular, lymphatic, and intracellular water and that is in a constant state of flux. The bound or *gel* phase is much less freely exchangeable and is composed of water that hydrates matrix materials such as glycosaminoglycans and mucopolysaccharides. The transcellular space, a third and smaller component of ECF, consists of water that is separated from other compartments by endothelial and epithelial barriers, including cerebrospinal, ocular, and synovial fluids, as well as fluid in the gastrointestinal (GI) tract. Under normal circumstances, fluid in the transcellular space is not easily exchangeable with that in other compartments.

Composition of Body Fluids

- 2 Sodium and potassium are the dominant cations in the body. Sodium is restricted primarily to the ECF and potassium to the ICF. Sodium content in the average adult is approximately 60 mEq/kg. Approximately 25% is confined to bone and is nonexchangeable. Of the exchangeable fraction, approximately 85% is in the ECF. Potassium, calcium, and magnesium make up the remainder of the cations present in the ECF. As mentioned, potassium is the dominant cation in the ICF. TBK is normally approximately 42 mEq/kg, and most of this potassium is intracellular and freely exchangeable. Magnesium and sodium ions also contribute to the cationic component of the ICF. These cations are balanced by phosphate and sulfate anions as well as bicarbonate and intracellular proteins (Table 10.2).

TABLE 10.2

ELECTROLYTE CONCENTRATIONS OF INTRACELLULAR AND EXTRACELLULAR FLUID COMPARTMENTS

	■ EXTRACELLULAR FLUID (mEq/L)		■ INTRACELLULAR FLUID (mEq/L)
	■ PLASMA	■ INTERSTITIAL	
Cations			
Na ⁺	140	146	12
K ⁺	4	4	150
Ca ²⁺	5	3	10 ⁻⁷
Mg ²⁺	2	1	7
Anions			
Cl ⁻	103	114	3
HCO ₃ ⁻	24	27	10
SO ₄ ²⁻	1	1	—
HPO ₄ ³⁻	2	2	116
Protein	16	5	40
Organic anions	5	5	—

Similarly, ECF cations are in electrochemical balance with chloride, bicarbonate, phosphate, and sulfate anions, although chloride is the major contributor to this balance. In addition, anionic proteins contribute to ion balance in plasma but not in interstitial fluid, which is essentially an ultrafiltrate of plasma that normally contains little protein. As a result, the content of both cations and anions in interstitial fluid is slightly higher than in plasma (see Table 10.2).

The Donnan equilibrium describes the relationship between solutions of permeable and impermeable complex anions when these anions are unevenly distributed across a semipermeable membrane. This special type of equilibrium exists between the ICF and ECF because of the high concentration of protein and nondiffusible phosphates in the cell. Interstitial fluid, by comparison, contains little protein. These impermeable intracellular negative charges tend to favor diffusion of permeant anions into the ECF. The Donnan equilibrium also exists across the capillary endothelial membrane because the concentration of protein is higher on the blood side of the capillary than on the interstitial fluid side. Thus, the concentrations of diffusible ions are not necessarily equal across these membranes because of the presence of these complex anions.

Concentration of Body Fluids

Despite the difference in composition between the ECF and ICF, the overall concentration of solutes in water in these fluids is identical. Transient concentration differences may develop; however, because water freely equilibrates between compartments, these quickly disappear. The concentration of solutes in the fluid compartments depends on the osmotic activity generated by the ion species contained in each compartment.

Osmotic Activity of Body Fluids

When two solutions are separated by a semipermeable membrane, water moves across the membrane to equalize the concentration of osmotically active particles to which the membrane is impermeable. The maintenance of osmotic equilibrium across a semipermeable membrane is based primarily on the number of solute particles rather than on the molar concentration of the solution on each side of the membrane. The correct measurement to reflect osmotic activity is made by multiplying the molar concentration of the substance by the number of particles into which it can freely dissociate in water. The unit of measurement of osmotically active particles is the osmole (Osm) or milliosmole (mOsm) rather than the conventional units of solute concentration such as milliequivalents per liter (mEq/L). When 1 mol of NaCl dissociates in water to Na^+ and Cl^- , it produces 2 Osm. The same relationship holds true of dissociating salts of multivalent ions such as calcium and magnesium. One mol of a nondissociating molecule, such as glucose, produces 1 Osm (1,000 mOsm). Osmolarity (mOsm/L) and osmolality (mOsm/kg water) define the osmotic activity of particles in solution. The measured osmolality of a solution may not equal the calculated osmolality if the ions do not totally dissociate. The osmotic coefficient of a solution describes the degree to which dissociation of the ions in solution occurs, and can be calculated as follows:

$$\text{Osmotic coefficient} = \frac{\text{observed (measured) osmolality}}{\text{calculated osmolality}}$$

Body fluids are aqueous solutions composed of water and various solutes within the different body fluid compartments. Because cells are bounded by a semipermeable membrane, adding free water to the fluid surrounding a cell causes water to move across the cell membrane to equalize the osmolality differential between the intracellular and extracellular com-

FIGURE 10.1. A: The equilibration of water from the extracellular to the intracellular space after the addition of free water to the extracellular fluid compartment. Osmolality transiently decreases in the extracellular compartment, causing water to move across the cell membranes into the intracellular space. B: Similar shifts after free water loss from the extracellular compartment. Water moves from the intracellular space to the extracellular space in response to the osmolal gradient that is established.

partments. On a larger scale, adding free water to the ECF of the body causes an immediate expansion of the extracellular space, followed by a redistribution of water into the intracellular compartment (Fig. 10.1A). Conversely, loss of free water from the extracellular space ultimately leads to a shift of water from the intracellular to the extracellular space (Fig. 10.1B). An osmotic gradient of just 1 mOsm generates a pressure gradient of 19.3 mm Hg.

Whereas *osmolality* defines the concentration of osmotically active particles in solution, *tonicity* refers to the effect of the particles on cell volume. Permeant solutes can freely cross cell membranes, whereas impermeant solutes cannot. Although permeant solutes contribute to the osmolality of a solution, they have no effect on tonicity because they contribute neither to oncotic gradients across cell membranes nor to alterations in cell volume. Sodium is an example of an impermeant solute that affects both osmolality and tonicity. Urea and ethanol are permeant solutes that contribute to osmolality but have little effect on tonicity because they distribute equally across membranes.

Both impermeant and permeant solutes can contribute to *hyperosmolar* and *hypo-osmolar* states. However, hypo-osmolar states are always accompanied by hypotonicity, whereas hyperosmolar states are not always associated with hypertonicity. There may be marked hyperosmolality without hypertonicity with elevation of blood urea nitrogen (BUN) levels because urea is a freely permeable molecule. In contrast, elevated levels of plasma glucose in diabetic patients are associated with hyperosmolality and associated hypertonicity. Insulin increases the transport of glucose across cell membranes, rendering these osmoles *ineffective* and reducing hypertonicity. Plasma hyperglycemia is associated with the movement of intracellular water to the extracellular space. This causes expansion of ECF and plasma volume and a consequent decrease in the concentration of plasma sodium. For every 100 mg/dL elevation in blood glucose, measured serum

sodium is calculated to fall 1.5 mEq/L, without an actual alteration of body sodium content. The osmotic diuresis caused by the elevated glucose level tends to normalize the serum sodium if adequate hydration is maintained. Some patients with uncontrolled diabetes also have marked hyperlipidemia. Because of this, the concentration of measured sodium falls. This condition is termed *pseudohyponatremia*.

Plasma osmolality (P_{osm}) is an excellent measure of total body osmolality. Osmolality differentials between fluid compartments are only transient because fluid shifts maintain isotonic conditions. Sodium is the predominant extracellular cation; thus, estimates of P_{osm} can be made by simply doubling the serum sodium concentration (serum $[\text{Na}^+]$):

$$P_{\text{osm}} (\text{mOsm/L}) = 2 \times \text{serum}[\text{Na}^+]$$

Because glucose and BUN may make significant contributions to P_{osm} in certain disease states, this formula is modified for glucose and for BUN:

$$P_{\text{osm}} (\text{mOsm/L}) = 2 \times \text{serum}[\text{Na}^+] + \text{glucose}/18 + \text{BUN}/2.8$$

Discrepancies of greater than 15 mOsm/L between calculated P_{osm} and P_{osm} measured in the clinical laboratory may be the result of the presence of other osmotically active particles, such as mannitol, ethanol, or ethylene glycol, or of a reduced fraction of plasma water secondary to high levels of myeloma proteins or hypertriglyceridemia.

Colloid Oncotic Pressure (Colloid Osmotic Pressure)

Plasma proteins are confined primarily to the intravascular space and contribute to the osmotic pressure developed between the plasma and the interstitial fluid. Normal plasma protein levels of 7 g/dL contribute approximately 0.8 mOsm/L. The van't Hoff equation is used to convert osmolality to osmotic pressure:

$$p = CRT$$

where p = osmotic pressure, C = osmolal solute concentration, R = gas constant, and T = absolute temperature. At body temperature, each milliosmole develops a 19.3-mm Hg pressure

gradient; thus, normal plasma protein concentrations generate a colloid oncotic pressure of 15.4 mm Hg ($19.3 \text{ mm Hg} \times 0.8 \text{ mOsm/L}$). When measured directly, plasma oncotic pressure equals approximately 24 mm Hg. The difference between the calculated and measured pressures is due to the shift in solute particles caused by the pressure of protein anions on one side of a semipermeable membrane as explained by the Donnan equilibrium.

Osmoregulation

- 3 Osmolality of body fluids stays fairly constant at approximately 285 to 295 mOsm/L as the result of tightly regulated water balance. Osmoreceptor cells in the paraventricular and supraoptic nuclei of the hypothalamus exert central control over the thirst mechanism and antidiuretic hormone (ADH) secretion from the posterior pituitary. In the presence of excess free water, ECF osmolality falls toward 280 mOsm/kg H_2O , thirst is inhibited, and ADH levels decline. In the absence of ADH, the permeability of renal collecting tubules to water is decreased, causing free water reabsorption to decrease and excretion to increase. Urine osmolality (U_{osm}) can decline to 100 mOsm/kg H_2O (Fig. 10.2). As excess free water is eliminated, P_{osm} begins to rise. Conversely, free water depletion causes an increase in P_{osm} . As P_{osm} approaches 295 mOsm/kg H_2O , thirst is stimulated as is ADH secretion. As ADH levels rise to approximately 5 pg/mL, the renal collecting tubules become maximally permeable to water. Water is reabsorbed from the collecting ducts in response to the concentration gradient developed in the renal medullary interstitium. Thus, the final concentration of urine depends on both the permeability of the collecting ducts (controlled by ADH secretion) and the concentration of the medullary interstitium. Maximal U_{osm} may approach 1,200 mOsm/kg H_2O . The net effect of these mechanisms is to promptly return high or low P_{osm} to normal. The high sensitivity of the osmoreceptors and the responsiveness of the ADH feedback system ensure that even small changes in P_{osm} result in marked alterations in urine concentration. This relation can be expressed as follows:

$$\text{Urine osmolality} = 95 \times \text{plasma osmolality}$$

FIGURE 10.2. The relation of plasma antidiuretic hormone (arginine vasopressin, or AVP) secretion to plasma (A) and urine (B) osmolality in healthy adults in varying states of water balance. (Reproduced with permission from Robertson GL, Berl T. Water metabolism. In: Brenner BM, Rector FC Jr, eds. *The Kidney*. Philadelphia, PA: WB Saunders; 1986:392.)

FIGURE 10.3. Effect of acute changes in blood volume or pressure on the osmoregulation of antidiuretic hormone (ADH; vasopressin). The heavy oblique line in the center represents the relation between plasma ADH and osmolality under normovolemic, normotensive conditions. The lines to the left and right show the shift in the relation when blood volume or blood pressure is acutely decreased or increased by the percentage indicated in the circles. (Reproduced with permission from Robertson GL. Physiology of ADH secretion. *Kidney Int* 1987;32(suppl 21):520.)

Thus, a 1-mOsm change in P_{osm} results in a 95-fold change in U_{osm} .

Angiotensin II and neural input from medullary baroreceptors can also influence ADH secretion and thirst, thus tying water balance to hemodynamic alterations. Relatively small changes in pressure have little effect on ADH secretion, but large decreases in pressure can cause tremendous increases in ADH release. Although changes in osmolality tend to have a much greater effect on ADH secretion than do hemodynamic changes, ADH responses to high or low P_{osm} can be profoundly affected by large changes in blood pressure (Fig. 10.3).

FLUID BALANCE

Sodium Concentration and Water Balance

Changes in TBW content are reflected by changes in the extracellular solute concentration. Because sodium is the primary extracellular cation and potassium is the predominant intracellular cation, the serum $[\text{Na}^+]$ approximates the sum of the exchangeable total body sodium (Na_e^+) and exchangeable TBK (K_e^+) divided by TBW:

$$\text{Serum}[\text{Na}^+] = \frac{\text{Na}_e^+ + \text{K}_e^+}{\text{TBW}}$$

Because total body solute content ($\text{Na}_e^+ + \text{K}_e^+$) remains relatively stable over time, changes in TBW content result in inversely proportional changes in serum Na^+ (Fig. 10.4). Thus,

FIGURE 10.4. Relation between serum $[\text{Na}^+]$ and the ratio of $(\text{Na}_e^+ + \text{K}_e^+)$ to total body water (TBW). (Reproduced with permission from Edelman IS, Liebman J, O'Meara MP, et al. Interrelationships between serum sodium concentration, serum osmolality and total exchangeable sodium, total exchangeable potassium and total body water. *J Clin Invest* 1958;37:1236.)

abnormalities in serum sodium are usually an indication of abnormal TBW content.

Volume Control

Changes in volume are detected both by osmoreceptors, which detect changes in P_{osm} , and baroreceptors, which are sensitive to changes in pressure. The osmoreceptors are responsible for the day-to-day fine-tuning of volume, whereas the baroreceptors contribute relatively little to the control of fluid balance under normal conditions.⁴ As mentioned previously, large changes in circulating volume (10% to 20% blood volume loss) can modify the osmoregulation of ADH secretion. Cardiac atrial baroreceptors control volume by means of sympathetic and parasympathetic neural mechanisms, whereas atrial natriuretic peptide (ANP) released by atrial myocytes in response to atrial wall distention may influence sodium-linked volume control by inhibition of renal sodium reabsorption.

Baroreceptor Modulation of Volume Control. *Effective circulating volume* describes that portion of the extracellular volume that perfuses the organs of the body and affects the baroreceptors. The effective circulating volume normally corresponds to the intravascular volume. However, in disease states such as congestive heart failure and arteriovenous fistula, where a smaller percentage of intravascular volume than normal is available for organ perfusion, effective circulating volume is reduced.

4 Changes in the effective circulating volume are sensed by volume receptors in the intrathoracic capacitance vessels and atria, pressure receptors of the aortic arch and carotid arteries, intrarenal baroreceptors, and hepatic and cerebrospinal volume receptors. These stretch receptors respond to changes in pressure and circulating volume and, through a complex system of neural and hormonal actions, alter sodium and water balance in the kidneys. Hormonal effects are mediated by the renin-angiotensin system, aldosterone, ANP, dopamine, and the renal prostaglandins.

Baroreceptor Function. The low-pressure baroreceptors of the intrathoracic vena cava and atria are located in vessels that are distensible and not affected by sympathetic stimulation; thus, they are ideally situated to detect changes in venous volume.⁵ These receptors send continuous signals through vagal afferent nerves to the cardiovascular control centers of the medulla and hypothalamus, which, in turn, send signals through parasympathetic and sympathetic fibers to the heart and kidneys. Changes in stretch of these vessels result in changes in the frequency of signal output from these receptors. Increases in atrial distention cause decreased nerve signal traffic, which ultimately causes increased sympathetic tone to the heart, which results in tachycardia and inhibition of sympathetic tone to the kidney. This leads to increased renal blood

flow and decreased tubular sodium reabsorption. Conversely, low volume in the intrathoracic vessels results in increased sympathetic tone to the kidneys, decreased renal blood flow, and increased sodium reabsorption.

Experimental evidence indicates that stimulation of the sympathetic innervation of renal arterioles and tubules results in decreased renal blood flow and increased tubular sodium reabsorption. The effects of sympathetic activity on renal sodium reabsorption are probably mediated both by direct tubular innervation and by β -adrenergic stimulation of renin production. Whether this effect is crucial to fine regulation of sodium balance under normal physiologic conditions is unclear. Renal denervation in conscious, unstressed animals results in minimal alteration of either blood flow or sodium reabsorption. The effects of renal denervation become much more marked with anesthesia administration or hypotension, suggesting that sympathetic effects on renal function may be important during periods of physiologic stress.

Arterial baroreceptors are located in the aortic arch and carotid arteries. They respond to changes in heart rate, arterial pressure, and the rate of rise in the arterial pressure. Arterial baroreceptors are important during periods in which there are extremes in the changes in arterial pressure characteristics, as occur during hemorrhage. They are probably not involved in controlling subtle volume or pressure changes. In addition to large-vessel baroreceptors, there are arterial baroreceptors in the afferent arterioles of the kidneys. These baroreceptors modulate renin secretion. Increases in transmural pressure cause suppression of renin release, and decreases in transmural pressure stimulate renin release.

Hormonal Mediators of Volume Control

Renin-angiotensin System. Renin is a 40-kD proteolytic enzyme that is released from the juxtaglomerular cells of afferent arterioles in the kidney in response to several stimuli. These include changes in arterial pressure, changes in sodium delivery to the macula densa of the distal convoluted tubule, increases in β -adrenergic activity, and increases in cellular cyclic adenosine monophosphate.

Renin cleaves the decapeptide angiotensin I from circulating angiotensinogen, an α_2 -globulin produced by the liver. Angiotensin I is cleaved to the octapeptide angiotensin II by angiotensin-converting enzyme (ACE), which is produced by vascular endothelial cells. One pass through the pulmonary microvasculature converts most angiotensin I to angiotensin II. Angiotensin II acts both locally and systemically to increase vascular tone. It also stimulates catecholamine release from the adrenal medulla, increases sympathetic tone through central effects, and stimulates catecholamine release from sympathetic nerve terminals. Angiotensin II affects sodium reabsorption by decreasing renal blood flow and glomerular filtration. This results in altered tubuloglomerular feedback, the mechanism by which changes in distal tubular NaCl delivery alter glomerular blood flow. Finally, angiotensin II increases sodium reabsorption by direct tubular action as well as by stimulation of aldosterone release from the adrenal cortex. The multiplicity of actions of angiotensin is depicted in Figure 10.5.

Aldosterone. Aldosterone is a mineralocorticoid produced in the zona glomerulosa of the adrenal cortex. Aldosterone increases renal tubular reabsorption of sodium. Aldosterone acts directly on the distal tubule cells by modifying gene expression and stabilizing the epithelial Na^+ channel in the open state and by increasing the number of channels in the apical membrane of these cells.⁶ By increasing protein production in these tubular cells, aldosterone induces an influx of sodium, which causes an increase in cellular $\text{Na}^+\text{-K}^+$ -adenosine triphosphatase activity. The net result is increased sodium reabsorption and increased potassium excretion. Although the primary regulator of aldosterone secretion is angiotensin II, aldosterone

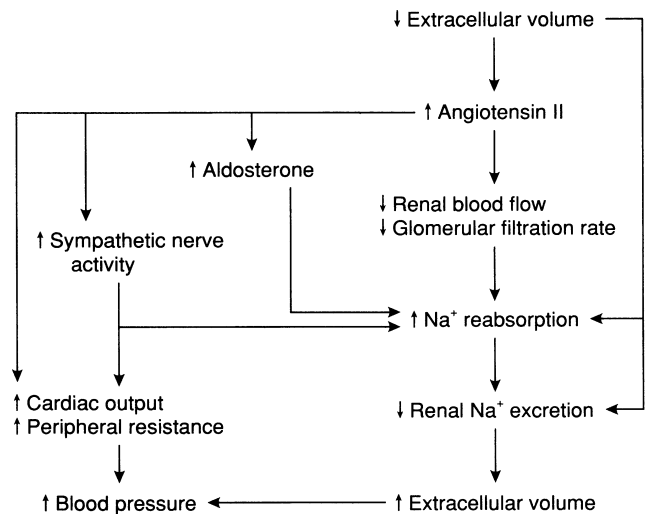

FIGURE 10.5. Multiple effects of increased angiotensin II release in response to the stimulus of decreased extracellular volume.

terone release is also stimulated by increased potassium levels, adrenocorticotrophic hormone, endothelins, and prostaglandins.

Atrial and Renal Natriuretic Peptides. ANP is synthesized and released by atrial myocytes in response to atrial wall distention. As mentioned previously, small changes in right atrial pressure produce large increases in plasma levels of ANP.^{7,8} There is evidence that ANP has a direct inhibitory effect on renal sodium reabsorption, which is probably maximal at the level of the medullary collecting tubules. Although pharmacologic doses of ANP can cause changes in both renal blood flow and glomerular filtration rate, physiologic levels do not appear to have any major effect on these parameters. Other active fragments of the ANP prohormone have been found to have natriuretic activity. The best described is urodilatin, also known as *renal natriuretic peptide*. Urodilatin is a peptide with ANP-like activity that was first isolated from human urine. It is synthesized and lumenally secreted by cortical collecting tubule cells. Like ANP, it is released in the kidney tubules in response to atrial distention and saline loading. It is at least twice as potent as ANP, acting in the distal nephron to cause a rise in intracellular cyclic guanosine monophosphate, leading to sodium, chloride, and water diuresis. ANP and other peptides may play an important role in controlling intravascular volume and water and electrolyte secretion.⁹

Renal Prostaglandins. Renal prostaglandins appear to play a role in volume control, although under normal physiologic conditions, this role may be minimal. Disease states such as sepsis and jaundice, or the induction of anesthesia, may make the contribution of the prostaglandins more pronounced.

Prostaglandin E_2 (PGE_2) and prostaglandin I_2 (PGI_2) appear to be the predominant prostaglandins produced in the kidney. PGE_2 is produced primarily by the interstitial cells of the renal medulla. The release of PGE_2 has been shown to depend on increases in interstitial pressure, which can be induced by changes in renal perfusion, ureteral obstruction, or alterations in oncotic pressure. Under these conditions, PGE_2 increases sodium excretion in the absence of changes in glomerular filtration rate. PGE_2 antagonizes the action of vasopressin (ADH) and inhibits ADH-induced sodium reabsorption along the medullary collecting duct and thick ascending limb. PGI_2 is produced by the glomeruli and endothelial cells of the kidney and is present in the greatest concentrations in the renal cortex. PGI_2 is

a vasodilator, and its effects on renal vascular resistance increase both renal blood flow and glomerular filtration rate. PGI₂ production is augmented by increases in angiotensin, catecholamines, and sympathetic tone and may act to counterbalance their vasoconstricting effects. Although under normal physiologic conditions inhibition of prostaglandin production has little effect on renal function, administration of nonsteroidal anti-inflammatory agents, which inhibit cyclooxygenase, to patients with conditions known to cause renal dysfunction (e.g., cirrhosis) can precipitate renal failure, presumably because of loss of the protective effects of the renal prostaglandins.¹⁰

Endothelins. Endothelins are peptide vasoconstrictors that are involved in volume and pressure regulation. Endothelin is produced and released by endothelial and other cells act on adjacent smooth muscle cells. In addition to increasing peripheral resistance, endothelin infusion has a direct inotropic effect on the myocardium. In contrast to its vasoconstrictive effects, endothelin stimulates the release of other vasoactive mediators, particularly endogenous vasodilators like nitric oxide, which act to limit its intense vasoconstrictor effect.

Endothelin exerts a complex influence on sodium and water exchange through varied interactions with many other hormones that govern fluid and electrolyte balance. One net effect of endothelin is a decrease in the filtered load of sodium in the kidney. This results in inhibition of water reabsorption and decreased sodium excretion. Endothelin increases ANP secretion, activates ACE, and inhibits renin release by the juxtaglomerular apparatus. At low doses, endothelin-1 produces a dose-dependent natriuresis and diuresis. Endothelin also modulates the biosynthesis of aldosterone, thereby inhibiting water reabsorption through aldosterone-controlled mechanisms. Vasopressin-mediated water reabsorption is also inhibited. Endothelin appears to have complex interactions with other regulators of renal perfusion and handling of water and electrolytes, which has stimulated research to evaluate the contribution of endothelin to the pathophysiology of various renal diseases.¹¹

Nitric Oxide. Nitric oxide is a short-lived free radical produced from L-arginine by nitric oxide synthases. Although this substance has numerous biologic functions that are beyond the scope of this chapter, including regulation of vascular tone and tissue blood flow,¹² its effects in the kidney as they relate to fluid and electrolyte homeostasis deserve mention. Nitric oxide is produced in renal smooth muscle cells, mesangial cells, tubules, and endothelial cells and participates in the regulation of renal hemodynamics and renal handling of water and electrolytes. Nitric oxide and PGI₂ each independently cause renal vasodilation in response to a variety of stimuli. Nitric oxide is important in the regulation of medullary (vasa recta) blood flow. Pressure-dependent sodium excretion is ablated by inhibitors like L-NG-monomethyl-arginine and restored with L-arginine. Nitric oxide also contributes to tubuloglomerular feedback, which modulates the delivery and reabsorption of sodium and chloride in the renal tubules. Nitric oxide synthase in macula densa cells is activated by tubular solute reabsorption to release nitric oxide as a vasodilating component of the tubuloglomerular feedback response. Nitric oxide also participates in regulating renin release by the juxtaglomerular apparatus. Finally, nitric oxide produced in the proximal tubule may mediate the effects of angiotensin on tubular reabsorption.¹²

Normal Water and Electrolyte Exchange

The body's normal homeostatic mechanisms control both the volume and composition of the fluid compartments such that a remarkably stable internal milieu is maintained. Surgical patients are prone to fluid and electrolyte abnormalities, not

TABLE 10.3

WATER LOSSES IN A 60- TO 80-kg MAN

	■ AVERAGE DAILY VOLUME (mL)	■ MINIMAL DAILY VOLUME (mL)
Sensible losses		
Urinary	800–1,500	300
Intestinal	0–250	0
Sweat	0	0
Insensible losses		
Lungs and skin	600–900	600–900

Adapted from Shires GT, Canizaro PC. Fluid and electrolyte management of the surgical patient. In: Sabiston DC, ed. *Textbook of Surgery*. Philadelphia, PA: WB Saunders; 1986:77, with permission.

only because of disease but also because perioperative fluid replacement may sidestep some of these homeostatic mechanisms. Although it is important to recognize and correct disease, trauma, and stress-related abnormalities, it is equally important to understand normal fluid and electrolyte balance and to avoid iatrogenic perturbations of these systems.

5 Normal Water Exchange. Water losses are both sensible (measurable) and insensible (unmeasurable). Sensible losses include losses through urine, stool, and sweat. Table 10.3 summarizes the normal sensible and insensible losses encountered in a 24-hour period. The volumes of these losses may vary considerably. Urinary loss usually varies in proportion to intake plus other losses. The minimal amount of water needed to excrete normal metabolic waste products is approximately 300 mL/d.

Water loss in stool is usually small, on the order of 150 mL/d, but may increase markedly in disease conditions. The GI tract has a net secretory action down to the level of the jejunum, and the reabsorptive capacity of the remainder of the small and large intestines keeps water loss by this route to a minimum. Bowel obstruction, severe diarrhea, and enterocutaneous fistulas are examples of conditions that may increase GI losses of water and electrolytes.

Sweat does not usually account for much of the daily water loss. Sweating is an active process involving the secretion of a hypotonic mixture of electrolytes and water, and it should be differentiated from the insensible water loss of evaporation from the skin.

Insensible water loss is the evaporatory loss of water from both the skin and the respiratory tract (see Table 10.3). Evaporatory skin losses are determined by the body surface area and temperature of the patient, as well as by the relative humidity of the environment. Evaporation through the skin functions as a mechanism for heat loss and is proportional to calories expended. Approximately 30 mL of water is lost for every 100 kcal expended. Respiratory exchange depends on the ambient temperature and the relative humidity as well as on the rate of air exchange. Respiratory water loss is also energy dependent; thus, at normal respiratory rates, 13 mL of water is lost for every 100 kcal expended. Overall, normal insensible water losses average approximately 8 to 12 mL/kg per day. Insensible water loss increases 10% for each degree of body temperature above 37.2°C (99°F). In addition, patients with tracheostomies who breathe unhumidified air lose additional free water. Conversely, patients who are on respirators or who breathe air that is 100% humidified have no respiratory losses and may gain free water.

A person normally consumes approximately 2,000 mL/d of water, although this quantity is highly variable. Approximately one third of this amount comes from water bound to food, and the remainder originates from free water intake. In addition, water may be gained when carbohydrates and proteins, which are kept in solution by water in the cell, are metabolized. Although this gain is usually minimal, catabolic states may increase the amount of oxidative free water gain to approximately 500 mL/d. To maintain proper fluid volumes, intake and excretion are well balanced through thirst mechanisms and the changes in renal excretion described earlier.

Normal Salt Exchange. In industrialized nations, daily sodium intake averages 100 to 250 mEq/d. This intake is balanced by losses through sweat, stool, and urine. Fine control of sodium balance is achieved by renal sodium excretion. In cases of hyponatremia, the kidney is capable of reducing urinary losses of sodium to less than 1 mEq/d. Conversely, urinary excretion can be increased to rates up to 5,000 mEq/d if necessary to achieve sodium balance. The normal sodium requirement is in the range of 1 to 2 mEq/kg per day.

Potassium balance in the body is also finely controlled. Because most potassium remains in the intracellular compartment, potassium homeostasis is maintained by a balance between intake and GI and renal losses and by a balance between extracellular and intracellular potassium. With a normal diet, approximately 40 to 120 mEq of potassium is ingested daily. Of this potassium, 10% to 15% is excreted in the feces, and the remainder is excreted in the urine. Normal daily potassium requirements are approximately 0.5 to 1 mEq/kg per day. Abnormal renal function markedly changes this figure; consequently, potassium intake must be minimized in patients with renal failure.

FLUID AND ELECTROLYTE THERAPY

Parenteral Solutions

Crystalloids. Solutions of electrolytes and water are collectively referred to as *crystalloids* and are the most widely used fluids for parenteral administration. Crystalloids are inexpensive, are highly effective for fluid maintenance and replacement, and have outstanding safety profiles. Crystalloid-induced hypercoagulability has been reported.^{13–15} Its causes are multifactorial and poorly understood. It can possibly be corrected with addition of fibrinogen¹⁶ and/or antithrombin III, but this does not often represent a significant clinical problem.

A number of electrolyte solutions are available for parenteral administration (Table 10.4). Selection of the appropri-

ate fluid requires assessment of the patient's maintenance fluid requirements, existing fluid deficits, and anticipated ongoing fluid losses. When a single solution does not accurately replace the electrolyte components of the losses or deficits, more than one type of solution may be administered. Ions such as potassium, magnesium, or calcium may be necessary and can be added to parenteral solutions to suit the patient's requirements.

Lactated Ringer solution is commonly used to replace losses of fluid with the ionic composition of plasma, such as blood loss, edema fluid, and small-bowel losses. It is ideal for the replacement of existing fluid deficits when serum electrolyte concentrations are normal. Although sodium content (130 mEq/L) is low compared with plasma, normal renal function usually ensures that the extra free water in this solution (150 mL/L) is excreted. Hyponatremia can occur with extended use of lactated Ringer solution or with use in patients who have impaired renal function, especially dilutional abnormalities such as those secondary to increased ADH secretion. Because the lactate anions in lactated Ringer solution are readily metabolized to bicarbonate in the liver, this solution does not appear to contribute to acidosis if tissue perfusion has been maintained or restored. Recent work comparing the DL racemic mixture of lactate in lactated Ringer solution with its L-isomer have implicated the D-isomer in leukocyte activation, although at present there are no compelling data to suggest that resuscitation with this solution increases the inflammatory response.¹⁷ Utilization of only the L-isomer in resuscitation solutions eliminates this theoretical problem.

Isotonic saline (0.9% or normal saline) contains 154 mEq of both sodium and chloride. Although this solution can be useful in patients with hyponatremia or hypochloremia, the excess of both sodium and chloride can lead to electrolyte and acid-base disturbances. Infusion of large volumes of 0.9% saline can lead to total body sodium overload and hyperchloremia. The added chloride load can result in a hyperchloremic metabolic acidosis or can aggravate preexisting acidosis. In addition, the pH of this solution and of the related solutions (0.45%, 0.33%, and 0.2% saline) is 4.0 to 5.0.

Following correction of deficits, less concentrated saline solutions are more appropriate to replace ongoing fluid losses (i.e., nasogastric tube losses) and for maintenance fluid therapy. Although the practical differences between 0.45%, 0.33%, and 0.2% saline solutions are not large, the specific fluid product selection is best determined by calculated requirements. These fluids are hypoosmotic and hypotonic with respect to plasma. In theory, rapid infusion of very hypotonic solutions can result in red blood cell lysis. For this reason, 5% dextrose (50 g of dextrose per liter) is added to these solutions to increase tonicity. In addition, 5% dextrose represents 200 kcal in each liter of solution.

TABLE 10.4

ELECTROLYTE CONTENT OF COMMONLY USED INTRAVENOUS CRYSTALLOID SOLUTIONS

■ SOLUTION	■ ELECTROLYTE (mEq/L)					...
	■ Na ⁺	■ K ⁺	■ Ca ²⁺	■ Mg ²⁺	■ Cl ⁻	
0.9% NaCl	154	—	—	—	154	—
0.45% NaCl	77	—	—	—	77	—
0.33% NaCl	56	—	—	—	56	—
0.2% NaCl	34	—	—	—	34	—
Lactated Ringer	130	4	4	—	109	28
3.0% NaCl	513	—	—	—	513	—
5.0% NaCl	855	—	—	—	855	—

Hypertonic saline solutions (HTSs) (3% NaCl and 5% NaCl) are generally used to replace sodium deficits in patients with symptomatic hyponatremia. However, these and even more concentrated (7.5% NaCl) solutions have also been used for resuscitation of hemorrhagic shock, head trauma, and burn patients.^{18,19} Hypertonic saline appears to increase intravascular volume in these patients more quickly than isotonic solutions, and the total resuscitation volume requirement may be decreased. When HTS is used for resuscitation of patients with severe sepsis, it has been shown to result in improvements in oxygen transport, cardiac output, and pulmonary capillary wedge pressure.¹⁸ The systemic and mesenteric oxygen extraction coefficient improves without worsening of other markers of perfusion. This is achieved by rapid mobilization of fluids from the intracellular compartment to the extracellular compartment. The osmotic gradient produced by HTS redistributes fluids from the perivascular and intracellular spaces to the intravascular space with consequent plasma volume expansion (up to fourfold). These cardiovascular and hemodynamic effects are short-lived, in general lasting from 60 to 120 minutes. The addition of colloids such as dextran or hetastarch can prolong the effect.

The osmotic effect of hypertonic saline may benefit patients with acute severe brain injury.²⁰ By reducing the water content of the brain, HTS can help to control intracerebral pressure after injury. In addition, HTS has immunomodulatory effects, which are well documented.²¹ HTS reduces the systemic inflammatory response syndrome (SIRS) and may attenuate multiple organ dysfunction syndrome (MODS).²¹ HTSs are not without adverse effects, however. Patients are at risk for electrolyte abnormalities such as hypernatremia. Extravasation into the soft tissues can produce significant soft tissue edema and even necrosis. Further clinical trials will be needed to determine the indications and efficacy of hypertonic solutions.

Colloids. Colloid plasma volume expander solutions offer the potential benefits of promoting retention of fluid in the intravascular space and of reducing excess interstitial fluid (edema). Worldwide, albumin and artificial colloids are relied on to varying degrees in fluid management of the surgical patient. In the United States, concerns regarding the effectiveness, cost, and potential complications of colloid administration have limited their use to specific clinical situations.

Albumin. Albumin (69 kD), derived from human plasma and heat-treated to reduce infection risk, is available in 5% and 25% solutions. These act by increasing plasma oncotic pressures and theoretically retarding or even reversing movement of water into the interstitial space. However, many of the conditions associated with edema are also associated with abnormalities in microvascular permeability. Examples include the pulmonary circulation in the adult respiratory distress syndrome, regional circulatory beds in burns or infections, and the systemic circulation in sepsis. Exogenously administered protein in colloid solutions can extravasate into the interstitial space and intensify, rather than decrease interstitial edema. The debate continues as recent large studies have added to the question of the benefits and disadvantages of resuscitation with colloids versus crystalloids.²² The SOAP trial (Sepsis Occurrence in Acutely Ill Patients) demonstrated increased mortality in intensive care unit patients treated with colloids, whereas the SAFE trial (Saline vs. Albumin Fluid Evaluation) found no overall difference in organ dysfunction or survival.²⁴

Hetastarch. Hydroxyethyl starches (HESs) are synthetic plasma expanders derived from hydrolyzed amylopectin, with variable degrees of substitution (DS) of hydroxyl groups for carbon groups on glucose molecules. HES is available commercially in the United States as a 6% solution of high-molecular-weight (450,000), highly hydroxyethyl substituted (DS 0.7) HES (hetastarch) in 0.9% saline. Hetastarch has been used as a

resuscitative solution in a variety of clinical settings with variable results. Coagulopathy and bleeding complications have been widely reported after administration of highly substituted, high-molecular-weight HES.^{25,26} This appears to be associated with reduced factor VIII and von Willebrand factor levels, a prolonged partial thromboplastin time, and impaired platelet function.²⁷ Because of its long half-life, coagulopathy does not quickly reverse after cessation of HES administration. Reports of renal insufficiency or renal failure after HES 450/0.7, HES 250/0.45 (Pentaspan), and HES 200/0.62 administration add to the concerns regarding overuse of these volume expanders, particularly in patients with preexisting renal impairment.

Hextend, a balanced 6% hetastarch (molecular weight [MW] 720,000) in lactated Ringer solution, has been forwarded as a much-improved alternate resuscitation product as compared to 6% hetastarch in saline. In a phase III trial of Hextend and 6% hetastarch in saline, Hextend was found to be as effective for resuscitation but without adversely affecting the coagulation profile.²⁸ Although the safety profile of this alternative colloid resuscitative fluid appears to be better than that of 6% hetastarch in saline, the data regarding its safety in situations of massive resuscitation are not clear. In a recent study using an experimental model of traumatic brain injury, Hextend was found to reduce fluid requirements, eliminate the need for mannitol, and improve neurologic outcome as compared to crystalloid and mannitol resuscitation. Furthermore, it had no adverse effect on coagulation.²⁹ In another recent experimental report, Hextend was found to have no significant platelet-inhibitory effects.³⁰

Low-molecular-weight, low-substituted (MW 130 kD; DS 0.4) HES (Voluven) has recently been introduced and demonstrated to have a far smaller effect on coagulation than other HES solutions.³¹ In addition, there is evidence that renal impairment does not occur after administration of HES 130/0.4, in contrast to the high-molecular-weight, highly substituted HES solutions.³² Although numerous reports now suggest that this type of alternative HES is a very good option when plasma volume expansion is indicated, the safety of wide use of large-volume Voluven administration remains to be demonstrated.

Dextrans. Dextrans are glucose polymers synthesized by *Leuconostoc mesenteroides* bacteria grown on sucrose media. These are available as synthetic plasma expanders in 40,000-MW (dextran 40; Rheomacrodex) and 70,000-MW (dextran 70; Macrodex) solutions. Although neither is used frequently for volume expansion, dextran 70 has been preferred because of its significantly longer half-life and better retention in plasma. The most accepted current use of dextran solutions is to lower blood viscosity. Both should be avoided in patients with known renal dysfunction, but dextran 40 has been shown to represent a particular risk for renal injury.³³ Anaphylactoid reactions can occur with either dextran 40 or 70.

Gelatins. Gelatin solutions produced from bovine collagen are effective as plasma volume expanders and are available outside the United States in urea-linked (Gelofusin) and succinate-linked (Haemaccel) formulations. Gelofusin has been used in similar clinical settings to HES, with similar clinical results, although one randomized trial comparing the two colloids in trauma patients suggested that HES (MW 250; DS 4.5) was more effective in reducing capillary leak.³⁴ Coagulopathy does not appear to be an issue with gelatins, although renal impairment has been reported with these colloids as well. Allergic reactions ranging in severity from pruritus to anaphylaxis can occur with both gelatin formulations.³⁵

Artificial Oxygen Carriers. Although the subject of transfusion is beyond the scope of this chapter, new developments in the area of oxygen-carrying synthetic volume expanders deserve brief mention. Early difficulties with perfluorocarbon-based solutions have increased the intensity of investigation to

develop hemoglobin-based oxygen-carrying (HBOC) solutions, and the results of recent clinical trials with these substances have been encouraging.³⁶ In the future, these solutions may prove beneficial when volume expansion in conjunction with increased oxygen-carrying capacity is required and will avoid the immunologic consequences of allogenic blood transfusions.

Goals of Fluid and Electrolyte Therapy

- 6** The goals of fluid therapy are to normalize hemodynamic parameters and body fluid and electrolyte concentrations. This is accomplished by correction of both volume and electrolyte abnormalities, as well as by replacement of both normal daily losses and additional ongoing losses associated with disease states and surgical treatments.

CORRECTION OF VOLUME ABNORMALITIES

Volume Deficits

Hypovolemia is common among surgical and trauma patients. Its occurrence may be related to direct loss of blood or other fluids but frequently occurs in the absence of external fluid loss. In critically ill patients, this can be due to vasodilation or diffuse capillary leak. Large volumes of fluid can be sequestered in extravascular spaces (third-space losses) as a consequence of inflammation, sepsis, or shock-related endothelial injury and increased endothelial permeability.³⁷ This situation is characterized by a movement of proteins and fluid from the intravascular to the interstitial compartment. Examples of disorders that cause third-space losses include bowel obstruction with edema of the bowel wall and transudation of fluid into the bowel lumen and pancreatitis with often massive retroperitoneal fluid extravasation. Third-space fluid in the interstitial space is poorly exchangeable with the intravascular compartment while the disease process persists. With the resolution of pathologic conditions and normalization of microvascular permeability, these fluid losses stop and sequestered fluid is returned to the intravascular space at variable rates.

Volume deficits can be either acute or chronic. Chronic volume deficits may manifest as decreased skin turgor, weight loss, sunken eyes, hypothermia, oliguria, orthostatic hypotension, and tachycardia. In addition, serum BUN and creatinine may be elevated, with a high BUN/creatinine ratio (above 15:1), and the hematocrit may be elevated as well. Assuming no change in red cell mass, the hematocrit can be expected to increase 6 to 8 percentage points for each liter deficit in intravascular volume. In this situation, urine concentration is usually high, and urine sodium excretion is low (<20 mEq/L Na^+). Unlike urine sodium levels, plasma sodium is not an indicator of intravascular volume. Plasma sodium concentration remains normal when fluid loss is isotonic, despite the volume of fluid lost.

Acute volume losses are usually manifested by changes in vital signs. If organ perfusion is compromised, urine output may be low. Attempts to quantify volume deficits are usually of little value. The volume of fluid required to restore blood pressure, heart rate, and urine output is the best estimate of what the volume deficit has been. Fluid resuscitation for hypovolemia is initiated with an isotonic solution such as lactated Ringer solution. Urine flow in critically ill patients is monitored with an indwelling Foley catheter with a goal of at least 0.5 mL/kg per hour output. After fluid resuscitation has been initiated, a thorough history and physical examination may help to determine the origins of the volume deficits, and the underlying causes can be appropriately addressed. Invasive

monitoring with a central venous or pulmonary artery catheter should be considered early in the resuscitation of elderly patients or patients with certain disease states such as severe cardiac disease or renal failure.

Volume Excess

Clinical manifestations of volume excess may occur with excessive parenteral volume administration, particularly in at-risk patients such as the elderly and those with cardiac disease. Volume overload can occur if appropriate adjustments to fluid therapy are not made. Possible manifestations of volume overload are weight gain, elevated central venous pressure (CVP), pulmonary congestion or edema, and peripheral edema. Intravascular volume excess is treated by volume restriction and use of loop diuretics.

MAINTENANCE FLUID THERAPY

Calculation of maintenance fluid replacement does not include replacement of either preexisting deficits or ongoing additional losses. Basal requirements for water and electrolytes are determined by sensible and insensible losses. Insensible water loss averages 8 to 12 mL/kg per day and increases 10% for every degree of body temperature above 37.2°C. Urinary and fecal losses must be added to this figure. Maintenance fluid volume requirements can be calculated based on body weight taking into account a larger per kilogram volume requirement of smaller body weight individuals (Table 10.5). A 10-kg child requires 100 mL/kg per day or 1,000 mL/d. A 70-kg man requires 1,000 mL/d for the first 10 kg ($100 \text{ mL/kg} \times 10 \text{ kg}$), plus 500 mL/d for the second 10 kg ($50 \text{ mL/kg} \times 10 \text{ kg}$), plus 1,000 mL/d for the last 50 kg ($20 \text{ mL/kg} \times 50 \text{ kg}$), for a total daily water requirement of 2,500 mL/d. In patients who may be intolerant of hypervolemia (i.e., cardiac disease, elderly patients), the requirement per kilogram over 20 kg is decreased to 15 mL/kg per day.

For maintenance therapy, 1 to 2 mEq/kg per day of sodium is required, with any administered excess managed by urinary sodium excretion. Potassium requirements are approximately 0.5 to 1 mEq/kg per day. If sodium is replaced at 2 mEq/kg per day and potassium is replaced at 1 mEq/kg per day, a 70-kg patient requires 2,500 mL of water containing 140 mEq of sodium and 70 mEq of potassium. Each liter of parenteral solution would contain 56 mEq of sodium and 28 mEq of potassium. The solution that best fits this patient's daily maintenance requirements is 0.33% saline solution (56 mEq/L Na^+). Potassium chloride can be added to each liter of solution (20 to 30 mEq/L), with appropriate adjustments for the patient's electrolyte and renal functional status.

- 7** Short-term maintenance therapy generally does not require addition of calcium, phosphate, or magnesium. However, in

TABLE 10.5

CALCULATION OF MAINTENANCE FLUID REQUIREMENTS

■ BODY WEIGHT	■ FLUID REQUIREMENT ^a	
For 0–10 kg	Give 100 mL/kg/d	A
For the next 10–20 kg	Give an additional 50 mL/kg/d	B
For weight >20 kg ^b	Give 20 mL/kg/d	C

^aMaintenance fluid requirements = sum of A + B + C.
^bFor elderly patients or patients with cardiac disease, this amount should be reduced to 15 mL/kg/d.

TABLE 10.6**ELECTROLYTE CONCENTRATIONS IN GASTROINTESTINAL SECRETIONS**

■ SECRETION	■ ELECTROLYTE (mEq/L)					■ RATE (mL/d)
	■ Na ⁺	■ K ⁺	■ Cl [−]	...	■ H ⁺

patients with chronic disorders, patients who experience significant volume shifts, or patients who require long-term parenteral fluid therapy, these electrolytes should be measured and corrected by the most practical route. If the enteral route is unavailable, these are administered in parenteral nutrition solutions along with trace elements, vitamins, and appropriate caloric sources.

REPLACEMENT OF ONGOING FLUID LOSSES

Once volume deficits have been replaced and maintenance fluids have been calculated and given, the overall fluid balance of the patient can be maintained by replacement of fluid losses beyond those considered to be maintenance. Ongoing losses from nasogastric tubes, stomas, fistulas, and other measurable sources are recorded during the course of care and can be replaced in fairly straightforward fashion. The electrolyte contents of these fluids can be estimated or measured and used to guide the choice of replacement fluid type (Table 10.6).

Intraoperative Fluid Therapy

Anesthesia interrupts normal baroreceptor reflexes, so the patient with volume depletion that was compensated preoperatively by increased vascular resistance and heart rate may become acutely hypotensive on induction of anesthesia. For this reason, adequate resuscitation before surgery is mandatory. During operative procedures fluid losses result from blood loss, third-space sequestration, and evaporative losses from open wounds. Operative blood loss can often be measured. Evaporative losses and shifts of intravascular fluid to the extravascular space (third space) cannot be measured but should be anticipated. Intraoperative replacement with isotonic solutions is usually accomplished at rates of 500 to 1,000 mL/h. Close monitoring of blood pressure and urine output, as well as judicious use of invasive monitoring techniques, aids the surgeon and anesthesiologist in avoiding problems associated with intraoperative volume depletion.

Postoperative Fluid Therapy and Monitoring

Fluid therapy during the postoperative period is adjusted to the patient's volume status at the completion of the operative procedure, as well as to anticipated ongoing fluid losses. Iso-

tonic solutions should be used for volume resuscitation during the early postoperative period. It is best not to give potassium supplements during this period, unless they are specifically required as indicated by serum electrolyte measurements, until adequate renal function is confirmed.

Routine monitoring of postoperative fluid status consists of serial vital signs and urine output measurements. Fluid intake and output data are recorded in the patient's medical record and used to plan ongoing fluid therapy. Weight should also be recorded daily. In the postsurgical patient, rapid fluctuations in weight are generally related to changes in TBW. Adequate fluid is given to maintain a urine output of greater than 0.5 mL/kg per hour. Urine specific gravity can also be measured and serves as an indicator of both volume status and renal ability to concentrate and dilute the urine. Urine specific gravity of greater than 1.010 to 1.012 indicates that the urine is being concentrated (relative to plasma), and a urine specific gravity of less than 1.010 indicates that dilute urine is being produced. Both volume depletion and cardiac failure are accompanied by increased urine concentration and low urine outputs. Urine specific gravity in the range of plasma (1.010 to 1.012) may indicate either adequate hydration or the inability of the kidneys either to dilute or concentrate the urine.

Renal failure in the postoperative period may be accompanied by low urine volumes (oliguric renal failure, <500 mL/d) or normal or high urine volumes (nonoliguric or high-output renal failure). Measurement of urine electrolytes and creatinine clearance can help clarify questions regarding volume status and renal function. CVP measurement can be used to more accurately assess volume status and guide fluid administration. Normal CVP may range from 5 to 12 mm Hg. Higher pressures usually indicate volume overload or cardiac failure, whereas pressures below this range indicate intravascular volume depletion. There are significant limitations to CVP measurement as a reflection of circulating volume, particularly in critically ill patients. Abnormalities of cardiac performance and vascular tone may confound interpretation of CVP measurements, and pulmonary artery catheterization may be required to resolve volume status questions.

ELECTROLYTES

Concentration Changes in Body Fluids

Volume excess or deficits are often isotonic but may be accompanied by changes in extracellular sodium concentration and osmolality. The mechanisms controlling normal osmoregulation

FIGURE 10.6. A: Isotonic dehydration. Extracellular fluid is lost, but sodium concentration and osmolality remain unchanged. There is no change in intracellular volume. B: Hypotonic dehydration caused by an extracellular fluid deficit with hyponatremia. Water moves into the intracellular space, causing further extracellular depletion and intracellular fluid (ICF) expansion. C: Hypertonic dehydration caused by loss of extracellular free water, resulting in hypernatremia. Water from the ICF shifts to the extracellular space, resulting in contraction of both ICF and extracellular fluid compartments.

may be affected by the same processes responsible for controlling volume. Volume depletion is the most common disorder of volume status encountered in surgical and trauma patients. These patients usually present with isotonic dehydration (Fig. 10.6A). In this condition, the volume lost is isotonic with plasma. Examples of isotonic volume deficits include blood loss, third-space losses, and GI losses. Volume depletion may also be accompanied by hypo-osmolar conditions (hypotonic dehydration; see Fig. 10.6B) and is often iatrogenic and the result of incomplete volume resuscitation with hypotonic solutions. Dehydration associated with hyperosmolar states (hypertonic dehydration; see Fig. 10.6C) is infrequent and usually indicates impaired consciousness and thirst mechanisms or a patient's inability to drink or obtain water. As mentioned previously, volume excesses often occur some time after hospitalization rather than at presentation. The most frequent concentration defect associated with volume excess is hyponatremia.

Hyponatremia

Causes. Hyponatremia may result from direct sodium loss or from dilution of sodium by excessive free water under hypovolemic, euvolemic, or hypervolemic conditions. Hyponatremia is frequently seen in the postoperative or postinjury period when ADH is elevated as a component of the normal stress response to injury. Inflammatory and stress cytokines such as C-reactive protein, interleukin-6, interleukin-1, and tumor

TABLE 10.7

CAUSES OF THE SYNDROME OF INAPPROPRIATE ADH SECRETION

Tumor hypersecretion of ADH	Lung Pancreas Bladder Prostate

Other	Infection Medication induced

ADH, antidiuretic hormone; CNS, central nervous system.

necrosis factor all increase ADH levels. Volume expansion due to increased ADH-stimulated free water reabsorption may stimulate natriuresis and exacerbate hyponatremia. Because volume expansion and hyponatremia diminish the effects of ADH on the collecting tubules, hyponatremia is usually self-limited under these circumstances, with serum sodium concentration rarely falling below 130 mEq/L unless exacerbated by exogenous free water administration.

The *syndrome of inappropriate ADH secretion* (SIADH) occurs as the result of ADH release under circumstances that are inappropriate to the patient's volume status. The diagnosis can be made when hyponatremia occurs in the presence of euvolemia (or hypervolemia) and normal renal and adrenal function. SIADH can be encountered in a wide range of clinical problems (Table 10.7). The diagnosis requires that the patient have a low plasma osmolality with a high urine osmolality secondary to high urinary sodium excretion in a low volume of urine. Treatment of hyponatremia in the setting of SIADH depends on the presence of symptoms, the severity of the hyponatremia, and its duration. In the acute setting most patients will respond to fluid restriction. Fluids are restricted to 50% to 75% of daily maintenance (700 to 1,000 mL/m² per day) and electrolytes should be measured every 6 to 8 hours. Patients who are symptomatic require aggressive treatment with hypertonic saline solutions such as 3% NaCl. Patients with chronic hyponatremia may not respond to water restriction and can benefit from drugs. Medication options include vasopressin receptor antagonists (VRAs) and osmotic loop diuretics. Demeclocycline, a tetracycline antibiotic, can be used to block vasopressin. A new class of peptide and nonpeptide VRA are in development. Currently, conivaptan (Vaprisol), a nonselective VRA, is the only drug of this class approved in the United States. Oral formulations such as relcovaptan, SSR-149,415, and V2 selective drugs (lixivaptan, mozvaptan, stavaptan, and tolvaptan³⁸) await approval by the Food and Drug Administration for use in the United States.

Hyponatremia can also be associated with low effective circulating volume. This most commonly occurs in edematous states or cirrhosis with ascites, but it can also result from dehydration with concomitant volume replacement with hypotonic solutions. Because of the low intravascular volume, renal plasma flow and glomerular filtration rate are low, resulting in increased sodium reabsorption by the kidneys. This renal compensation may not be sufficient to correct the abnormality.

Although hyponatremia most often results from excess free water, it can occur in the presence of excess solute, as previously

TABLE 10.8**SYMPTOMS OF HYPONATREMIA**

	Muscle cramps

described, with increased P_{osm} in hyperglycemic conditions (pseudohyponatremia). Other types of solute may contribute to hyperosmolality and water shifts from the intracellular to the extracellular space, with consequent hyponatremia. These include exogenously administered or ingested mannitol, ethanol, methanol, or ethylene glycol. In addition to shifts in water, cellular exchange of potassium for sodium as a compensatory mechanism for potassium loss may result in hyponatremia. In both hyperosmolar and hypokalemic conditions, total body sodium remains normal.

Finally, hyperproteinemia and hyperlipidemia can cause falsely low sodium values. This pattern of *pseudohyponatremia* is due to an anomaly of laboratory measurement of sodium and is not accompanied by any symptoms attributable to hyponatremia.

Clinical Features. Chronic hyponatremia is often asymptomatic until serum $[\text{Na}^+]$ falls below 110 to 120 mEq/L. A more acute drop in serum $[\text{Na}^+]$ to the 120 to 130 mEq/L range may result in central nervous system (CNS), musculoskeletal, or GI symptoms (Table 10.8). Symptoms related to the CNS result largely from cellular water intoxication, and permanent CNS injury can occur if hyponatremia is left untreated.

Diagnosis. Differentiating the causes of hyponatremia may be difficult. Once hyperosmolar hyponatremia (caused by hyperglycemia, mannitol administration, or radiologic contrast medium) has been excluded and pseudohyponatremia has been eliminated from the differential diagnosis, the clinician must determine whether the effective circulating volume is low (hyponatremic dehydration) or normal.

Hyponatremic dehydration may be caused by renal or extrarenal sodium losses. Renal sodium losses are usually the result of diuretic use, chronic renal failure, adrenal insufficiency, or a defect in aldosterone secretion. The hallmark of these disorders is a urine sodium level above 20 mEq/L in the face of hyponatremia. This is in contradistinction to extrarenal sodium loss such as that caused by vomiting; diarrhea; or fluid loss through nasogastric tubes, fistulas, or drains. The dehydration resulting from these conditions causes increased renal sodium reabsorption and urine sodium levels below 20 mEq/L. Normal or high effective circulating volume in combination with hyponatremia is almost always caused by SIADH or by increased sensitivity of the renal collecting tubules to the action of normal levels of ADH.

Treatment. Hypovolemic patients with hyponatremia can frequently be treated by rehydration with isotonic saline or lactated Ringer solution because symptoms in this situation are

often caused by dehydration rather than hyponatremia. Overly rapid normalization of volume may lead to hypernatremia, and serum $[\text{Na}^+]$ must be serially monitored during volume replacement. Most surgical patients with hyponatremia are euvolemic or hypervolemic. Asymptomatic patients in this category are best treated by free water restriction.

Patients who have significant symptoms require aggressive treatment with a clear recognition that overzealous therapy may lead to CNS injury. Rapid infusion of hypertonic saline may result in central pontine myelinolysis and the quadriplegia, dysarthria, and dysphasia of the “locked in” syndrome. This risk is greatest in patients who have been hyponatremic for longer than 48 hours. In these patients, 3% or 5% saline solution is given relatively slowly to increase serum $[\text{Na}^+]$ at a rate not exceeding 0.5 mEq/L per hour. The amount of sodium needed to increase the serum $[\text{Na}^+]$ to a desired level can be calculated as follows:

$$\text{Na}^+ \text{ required (in mEq)} = (\text{desired}[\text{Na}^+]_s - \text{actual}[\text{Na}^+]_s) \times \text{TBW}$$

where $[\text{Na}^+]_s$ = serum sodium concentration. For example, a 70-kg patient has been hyponatremic for more than 48 hours and has a serum sodium level of 120 mEq. Correction of hyponatremia during the first 24 hours is limited to 0.5 mEq/L per hour \times 24 hours = 12 mEq/L. Assuming TBW 60% of body weight:

$$\text{Na}^+ \text{ required} = (132 - 120) \times (0.6[70]) = 504 \text{ mEq}$$

Because 5% saline contains 850 mEq/L of sodium, the volume of 5% saline required to provide 504 mEq of sodium in the first 24 hours of treatment is as follows:

$$504 \text{ mEq} / 850 \text{ mEq} = 0.593 \text{ L } 5\% \text{ saline}$$

For more acute symptomatic hyponatremia (<48 hours' duration), more rapid treatment may be used. Five percent or 3% hypertonic saline may be administered at a rate of 1 to 2 mEq/L per hour. Hyperacute hyponatremia, which may result from inadvertent infusion of large volumes of water or from dialysis accidents, can be treated at rates of 5 mEq/L per hour. The treatment goal is to achieve a serum sodium level above 125 mEq/L or to achieve resolution of symptoms.

Hypernatremia. Hypernatremia is a less common problem in surgical patients than hyponatremia but can occur due to a number of causes (Table 10.9). Although hypernatremia is

TABLE 10.9**CAUSES OF HYPERNATREMIA**

VOLUME STATUS	CAUSE
Low	Free water loss
	Insensible—skin, respiratory
	Gastrointestinal loss
	Excessive hyperosmotic peritoneal dialysis
	Renal
Normal	Diuretics, diabetes insipidus, nonoliguric renal failure
	Same as “Low” volume status but with improper correction
High	Free water loss
	Increased mineralocorticoids—hyperaldosteronism, hypercortisolism
	Iatrogenic
	Excessive sodium administration

usually the result of excessive free water loss associated with hypovolemia, it can also occur in euvolemic and hypervolemic states. Euvolemic hyponatremia tends to occur for the same reasons as in hypovolemic situations, with the added factor of improper correction of free water loss (i.e., with sodium-containing fluids). Water loss may be due to nonrenal or renal causes. Nonrenal free water losses can be characterized as insensible as in respiratory losses in patients with tracheostomies who breathe unhumidified air or skin losses in patients with high fevers. Large volumes of free water can also be lost when hypertonic glucose solutions are used for peritoneal dialysis. *Diabetes insipidus*, seen most frequently in head trauma or neurosurgical patients, is due to depressed secretion of ADH. The free water diuresis in this condition can at times be massive.

Hyponatremia can also be caused by increased total body content of sodium, which is usually related to exogenous administration of sodium. Infusion of excessive amounts of sodium bicarbonate during acute resuscitation from cardiopulmonary arrest is frequently associated with subsequent hyponatremia. Administration of solutions containing large amounts of sodium for replacement of free water deficits may also lead to hyponatremia.

Clinical Features. Moderate degrees of hyponatremia are tolerated well, and symptoms rarely develop unless serum $[\text{Na}^+]$ levels exceed 160 mEq/L or serum osmolality exceeds 320 to 330 mOsm/kg. Rapid onset of hyponatremia is associated with earlier onset of symptoms. The symptoms of hyponatremia are related to the hyperosmolar state. Cellular dehydration occurs as water passes into the extracellular space. CNS effects predominate. The most common symptoms are restlessness, irritability, ataxia, fever, tonic spasms, and seizures. Subarachnoid hemorrhage may also occur.

Treatment. Once hyponatremia becomes symptomatic, it is associated with significant morbidity and mortality if prompt treatment is not instituted. Rapid correction carries a significant risk of cerebral edema and brainstem herniation. In chronic hyponatremia, the cells in the brain gradually adapt by increasing intracellular osmotic solute content, thereby regaining cellular volume. These cellular changes are not readily reversed. A sudden decrease in extracellular sodium concentration, and therefore osmolality, results in cell swelling. Because chronic hyponatremia is relatively well tolerated, there are few advantages to correcting the free water deficit rapidly. Free water is administered to correct serum $[\text{Na}^+]$ at a rate not exceeding 0.7 mEq/L per hour. The amount of water required to correct a hyponatremic state depends on the free water deficit, the insensible free water losses, and the urinary free water excretion rate. The water requirement to replace the free water deficit can be calculated using the following formula:

$$\text{water requirement} = \frac{\text{desired change in } [\text{Na}^+]_s \times \text{TBW}}{\text{desired } [\text{Na}^+]_s}$$

For example, a 70-kg patient with a TBW of 42 L (TBW 60% of body weight) has a serum sodium of 170 mEq/L. The maximum desired change in serum sodium over 1 day would be approximately 16 mEq (0.7 mEq/L per hour). Therefore, water requirement = $16 \times 42/154 = 4.3$ L.

The desired level of serum sodium would not be achieved unless insensible losses (approximately 8 mL/kg per day) and urinary free water losses were also replaced. Urinary losses of free water can be determined by calculating free water clearance:

$$\text{CH}_2\text{O} = V - C_{\text{osm}} V - \frac{U_{\text{osm}} \times V}{P_{\text{osm}}}$$

where CH_2O = free water clearance rate, C_{osm} = osmolar clearance rate, V = urine flow rate, and U_{osm} and P_{osm} = urine and plasma osmolalities, respectively.

The U_{osm} and P_{osm} can be estimated by the total sodium and potassium concentrations. Therefore,

$$\text{CH}_2\text{O} = V - \frac{(U_{\text{Na}} + U_{\text{K}}) \times V}{[\text{Na}^+]_s}$$

where U_{Na} and U_{K} = urinary sodium and potassium concentrations, respectively. A positive number signifies net free water loss and adds to the water requirement, whereas a negative number indicates free water absorption and is subtracted from the water requirement. Thus, the total water requirement to achieve the desired decrease in serum $[\text{Na}^+]$ is the sum of the calculated water deficit plus the calculated insensible water loss plus the urinary free water clearance.

Compositional Changes in Body Fluids

Potassium. Potassium is the major intracellular cation and is the major determinant of intracellular osmolality. Normally, intracellular potassium concentration is approximately 150 mEq/L, whereas extracellular potassium levels range from 3.5 to 5 mEq/L. Because of the large difference between intracellular and extracellular potassium concentrations, a transmembrane potential is generated. Alterations in the potassium concentration gradient have profound effects on transmembrane potential and consequently on cellular function. This is especially true for cardiac, skeletal, and smooth muscle. The membrane potential (E_m) developed in cells is described by the Nernst equation:

$$E_m = -\log_{10} [K_i]/[K_e]$$

where $[K_i]$ and $[K_e]$ = intracellular and extracellular potassium concentrations, respectively.

Normally, the membrane potential of cells is approximately -90 mV as produced by a $[K_i]/[K_e]$ ratio of 30:1. Intracellular potassium levels are relatively stable, but extracellular potassium levels are often altered in pathologic situations. Overall potassium balance is determined by potassium intake and by renal and extrarenal excretion.

Approximately 90% of ingested potassium is excreted in the urine, and the remainder (5 to 10 mEq/d) primarily in feces. Most potassium filtered by the glomerulus is reabsorbed in the proximal tubule, so that net excretion is determined by the amount of potassium secreted by the distal tubule and collecting duct of the nephron. In these nephron segments, movement of potassium into the tubular lumen is determined by the difference between intracellular and luminal fluid K^+ concentrations, the permeability of the luminal cell membranes to K^+ , and the electrical potential gradient across the luminal cell membrane. Potassium secretion is stimulated by increased urine flow in the distal nephron segments, increased sodium delivery to these segments, high plasma potassium concentrations, and alkalosis. In addition, humoral factors, including aldosterone, vasopressin, and β -adrenergic agonists, stimulate renal excretion of K^+ . Because of the central role of the kidneys in potassium excretion, renal failure can lead to hyperkalemia. Nonrenal losses may increase greatly in hyperkalemic states or in renal failure.

Extracellular potassium levels can be greatly influenced by the acute shifts of potassium into or out of the cells. Insulin causes potassium to move into the cell, inducing a change in membrane potential and stimulating glycolysis. Alkalosis causes K^+ to shift into cells in exchange for H^+ . Conversely, acidemia induces the cellular exchange of intracellular K^+ for extracellular H^+ . A redistribution of K^+ into the ECF can also occur in hyperosmolar conditions because the movement of

water into the extracellular compartment causes “solvent drag,” which may increase the flux of potassium.

Hyperkalemia

Causes. Hyperkalemia rarely develops from excessive potassium intake given the high capacity for renal potassium excretion. In the surgical patient, diminished renal function is probably the most common problem leading to hyperkalemia. Both chronic and acute renal failure result in a defect in potassium excretion. Nonoliguric renal failure may lead to hyperkalemia despite apparently adequate urine output. Serum potassium levels may increase by 0.3 to 0.5 mEq/L per day in noncatabolic patients with acute renal failure, but this level can increase to 0.7 mEq/L per day or more in catabolic patients or those with other sources of potassium intake. Hospitalized patients may also receive excess potassium in intravenous fluids and total parenteral nutrition formulas. Less obvious sources include medications that are bound to potassium (i.e., β -lactam antibiotics).

In patients with chronic renal disease, potassium balance is normalized by increased colonic potassium excretion, as well as increased potassium excretion per functional nephron. Infusion of cationic amino acid solutions, such as arginine and lysine, can be associated with hyperkalemia because these amino acids are taken up by cells in exchange for potassium. Patients with impaired renal function or diabetes are also at risk for developing hyperkalemia when given ACE inhibitors and/or angiotensin or aldosterone receptor inhibitors.³⁹

Cellular disruption with release of potassium may result in hyperkalemia. The classic example of this is hyperkalemia associated with crush injuries. Reperfusion of ischemic limbs can lead to substantial elevations in potassium when reflow of blood washes out the byproducts of ischemia-induced cell lysis. Hyperkalemia may also occur when potassium is released from lysed erythrocytes in large hematomas or after massive blood transfusion. Similarly, potassium release from tumor lysis may result in increased serum potassium. Hyperkalemia can also be associated with the depolarizing muscle relaxants (e.g., succinylcholine). Although unusual, hyperkalemia can also result from absorption of potassium after the use of solutions containing high potassium levels, such as cardioplegia solutions or organ preservation solutions.

Clinical Features. The clinical manifestations of hyperkalemia are primarily related to membrane depolarization caused by a decrease in the $[K_i]/[K_e]$ ratio. The most life-threatening manifestations are related to the cardiac effects of membrane depolarization. Mild hyperkalemia results in peaked T waves on the electrocardiogram (ECG) and can cause paresthesias and/or weakness. More severe forms of hyperkalemia cause flattened P waves, prolongation of the QRS complex, and deep S waves on the ECG. Ventricular fibrillation and cardiac arrest can follow. Neuromuscular manifestations of severe hyperkalemia include weakness progressing to flaccid paralysis.

Treatment. The treatment of hyperkalemia is dictated by the serum level and by ECG changes or symptoms. Severe hyperkalemia with ECG abnormalities requires urgent treatment. The effects of hyperkalemia on membrane potentials can be reduced by increasing calcium levels. Rapid infusion of 10% to 20% calcium gluconate may be lifesaving. The effects are transient and usually last approximately 30 minutes. Administration of sodium bicarbonate is another temporary measure. The increase in serum sodium antagonizes the effects of hyperkalemia on the membrane potential, whereas the increase in extracellular pH shifts potassium into the cells. Movement of potassium into the intracellular compartment can also be achieved by giving 10 to 20 units of regular insulin. To avoid insulin-induced hypoglycemia, 25 to 50 g of glucose (50 to 100 mL of 50% glucose solution) is administered concurrently.

Definitive therapy of hyperkalemia requires increasing potassium excretion. This may be accomplished by the administration of K^+/Na^+ exchange resins such as sodium polystyrene sulfonate (Kayexalate). The usual oral dose is 40 g dissolved in 20 to 100 mL of sorbitol. Each gram removes approximately 1 mEq of potassium. Kayexalate can also be given as a retention enema in a dose of 50 to 100 g in 200 mL of water. Retention of the enema may be facilitated by inflating the balloon of a Foley catheter in the rectum. Each gram removes approximately 0.5 mEq of potassium. Peritoneal dialysis or hemodialysis is indicated for severe hyperkalemia and for patients with renal failure.

Hypokalemia

Causes. Hypokalemia can be caused by TBK depletion secondary to decreased potassium intake, increased extrarenal potassium losses, or increased renal potassium losses. Normally, hypokalemia is not secondary to diminished potassium intake, although intravenous fluid replacement with potassium-free solutions for prolonged periods can result in hypokalemia, especially in patients with ongoing potassium losses.

Decreased serum potassium levels may also be caused by redistribution of potassium into the intracellular space. Acute increases in blood pH secondary to bicarbonate administration during resuscitation can cause acute hypokalemia, as can administration of insulin to hyperglycemic diabetic patients. Causes of hypokalemia are listed in Table 10.10.

Clinical Features. Symptoms of hypokalemia, like those of hyperkalemia, are manifestations of disturbances in the $[K_i]/[K_e]$ ratio with resultant alterations in membrane potentials. As potassium levels fall below 2.5 mEq/L, muscle weakness is common. Severe hypokalemia can cause paralysis involving the muscles of respiration. Intestinal peristalsis can be impaired and result in intestinal ileus. Cardiac muscle abnormalities are reflected by the predisposition to digitalis intoxication; the development of cardiac arrhythmias, including ventricular fibrillation; and sensitization to epinephrine. ECG abnormalities include flattened T waves, depressed ST segments, prominent U waves, and prolongation of the QT interval. Renal changes include decreased renal blood flow and glomerular filtration rate. These effects may be relatively minor, and they may be accompanied by polyuria, polydipsia, metabolic alkalosis, and sodium retention. Decreased peripheral vascular resistance with ensuing hypotension may be due to a decrease in vascular sensitivity to angiotensin II.

Treatment. The primary treatment of hypokalemia is potassium replacement, although the patient's acid–base balance should be considered before initiating therapy. The route and rate of potassium replacement depends on the presence and severity of symptoms. Since potassium is primarily an intracellular ion,

TABLE 10.10

CAUSES OF HYPOKALEMIA

- Shift of potassium to the intracellular space
- Acute alkalosis
- Administration of glucose and insulin
- Catecholamines
- Increased gastrointestinal loss
- Diarrhea
- Mucus-secreting colon tumors (villous adenoma)
- Excessive renal loss
- Metabolic alkalosis
- Magnesium deficiency
- Hyperaldosteronism (adrenal adenoma or hyperplasia)

potassium deficits cannot be directly calculated but they can be estimated. On average, a reduction in serum potassium of 1 mEq/L represents a TBK deficiency of approximately 100 to 200 mEq. Potassium should be given orally if possible. Oral formulations include potassium salts such as potassium chloride, potassium phosphate, and potassium bicarbonate. Potassium should be administered intravenously if the symptoms are severe, if the serum concentration is below 2 mEq/L, or if the patient is unable to take oral potassium. Intravenous potassium is highly irritating to peripheral veins and should not be administered at a rate greater than 20 mEq/h and ideally should be administered at 10 mEq/h or less. Under close cardiac supervision and continuous monitoring in emergent circumstances, as much as 40 mEq/h can be administered via a central line.

Calcium. Calcium is a divalent cation found in abundance in the human body. Approximately 99% of total body calcium is located in bone in the form of hydroxyapatite crystals. Although the bulk of this calcium is not readily exchangeable, the calcium on the surface of bones can be exchanged and serves as the major store of calcium for maintenance of calcium balance. Calcium homeostasis depends on exchange of calcium between bone and ECF, renal excretion, and intestinal absorption. These three processes are controlled to a great extent by parathyroid hormone (PTH).

The total plasma calcium concentration is approximately 10 mg/dL. In ECF, calcium exists in three forms: ionized, nonionized, and protein bound. Ionized calcium, which makes up approximately 45% of total calcium, is responsible for most physiologic actions of calcium in the body, and its level is tightly controlled by regulatory mechanisms. Normal serum concentration of ionized calcium is approximately 4.5 mg/dL. Some nonionized calcium is complexed with nonprotein anions, including phosphate and citrate, and does not easily dissociate. These molecular forms make up only 15% of the total calcium present in plasma. Approximately 40% of extracellular nonionized calcium is bound to proteins. Most is bound to albumin, with the remainder bound to α - and β -globulins.

Changes in either plasma protein levels or pH can alter the proportion of calcium in the ionized state. The protein binding of calcium is pH dependent because of competition by H^+ for protein-binding sites. Prompt correction of changes in ionized calcium by various homeostatic mechanisms usually prevents symptoms from occurring, but rapid changes in pH can result in symptoms. The change in ionized calcium can be predicted if the changes in pH and protein concentrations are known. A 0.1 change in pH alters protein-bound calcium by 0.17 mg/dL in the same direction as the pH change. Thus, acidosis decreases protein-bound calcium levels and increases ionized calcium levels. Similarly, a change in albumin concentration of 1 g/dL changes protein-bound calcium by 0.8 mg/dL in the same direction. Because little of the calcium is bound to globulins, changes in globulin concentration of 1 g/dL change protein-bound calcium by only 0.16 mg/dL.

Despite a 10,000-fold concentration gradient with the ECF, intracellular calcium concentration is normally maintained at extremely low levels, 10^{-7} mol/L. This is accomplished by active transport of calcium out of the cell and by sequestration of calcium in mitochondria and the endoplasmic reticulum. Calcium influx occurs through calcium channels, and cytosolic calcium is often bound to specific calcium-binding proteins such as calmodulin. These control mechanisms are key to the central role of calcium as a second messenger in multiple cellular functions such as neural transmission, muscle contraction, and enzyme regulation.

Calcium Homeostasis. Calcium homeostasis is maintained through a balance of bone exchange, renal excretion, and intestinal absorption. All of these functions are controlled to a great degree by PTH. Of these three homeostatic mechanisms, calcium exchange with bone is the most important. Decreased

levels of ionized calcium lead to increases in PTH and increases in 1,25-dihydroxyvitamin D_3 , both of which stimulate bone absorption by increasing osteoclastic activity. Increased levels of ionized calcium result in decreased PTH and 1,25-dihydroxyvitamin D_3 , which decreases bone absorption. In addition, an elevated ionized calcium concentration results in increased calcitonin and 24,25-dihydroxyvitamin D, which increases osteoblastic activity.

Intestinal absorption of calcium depends primarily on 1,25-dihydroxyvitamin D_3 , which stimulates calcium absorption from all parts of the small intestine. Renal excretion of calcium is regulated by PTH and vitamin D, which increase distal tubular reabsorption of calcium, and by calcitonin, which inhibits calcium reabsorption. Both metabolic and respiratory alkalosis can increase calcium excretion. Acidosis has the opposite effect. The fundamentals of the regulation of calcium homeostasis are depicted in Figure 10.7.

Hypercalcemia

Causes. The most common causes of hypercalcemia are hyperparathyroidism and malignancy. Hyperparathyroidism is termed *primary* when one or more parathyroid glands produce inappropriately elevated amounts of PTH in relation to the serum calcium level. This is the result of a parathyroid adenoma in approximately 80% to 90% of cases. Chief cell hyperplasia accounts for an additional 15% of cases, whereas parathyroid cancer is responsible for less than 1% of cases. In secondary hyperparathyroidism, elevated PTH secretion occurs because of an abnormality of an organ system other than the parathyroid glands. Usually this is the result of renal failure, although Paget disease, osteogenesis imperfecta, and multiple myeloma are other known etiologies. Renal failure can contribute to hypocalcemia in several ways: (a) poor renal excretion of phosphate produces rises in serum phosphate levels that result in decreased serum calcium levels, (b) gut absorption of calcium is decreased because of a deficiency in renal vitamin D metabolism, and (c) diseased kidneys are not capable of clearing the breakdown products of PTH. Tertiary hyperparathyroidism is the development of parathyroid hyperplasia with autonomous PTH production. As a result, up to 30% of patients with prerenal transplantation hyperparathyroidism have persistent elevations in the PTH and calcium after renal transplantation despite the fact that renal function has returned toward normal.

Hypercalcemia can be caused by malignant disease, either because of bony destruction from metastases, or from autonomous tumor secretion of PTH-like substances that alter calcium homeostasis. Common causes of hypercalcemia associated with bone destruction include multiple myeloma, lymphoma, or metastatic breast carcinoma. Interleukin-1, colony-stimulating factor, and tumor necrosis factor have been implicated as local mediators of the osteolytic activity associated with tumor metastases. Tumors that elaborate humoral factors resulting in hypercalcemia are primarily squamous cell carcinomas of the head and neck, esophagus, lung, kidney, and genitourinary tract. Secretion of PTH-like peptides, prostaglandins, transforming growth factor, and vitamin D metabolites has been reported. Humorally mediated hypercalcemia may also occur with metastatic tumors, especially breast carcinoma.

Other causes of hypercalcemia include the use of thiazide diuretics, acute adrenal insufficiency, granulomatous disease, milk-alkali syndrome, hyperthyroidism, and prolonged immobilization in otherwise young and healthy patients.

Clinical Features. The clinical manifestations of hypercalcemia depend on both the severity and duration of the abnormality. Neuromuscular effects may be the earliest manifestations and include muscle fatigue, weakness, personality disorders, psychoses, confusion, depression, and coma. Cardiovascular effects are less prominent, with hypertension being the most frequent problem encountered. ECG changes include shortening

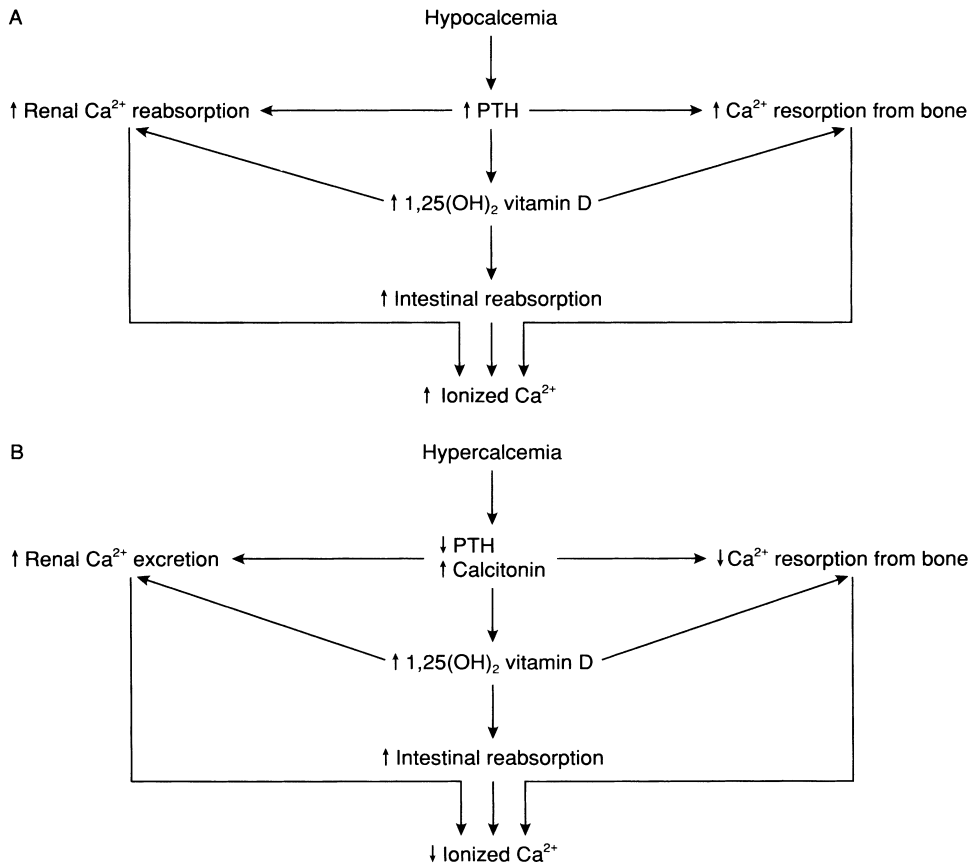

FIGURE 10.7. Effects of hypocalcemia (A) and hypercalcemia (B) on the mediators of calcium homeostasis. PTH, parathyroid hormone.

of the QT interval. GI side effects, such as nausea, vomiting, and abdominal pain, are not uncommon. Pancreatitis and increased gastric acid secretion with ulcer formation have also been reported.

The renal side effects of chronic hypercalcemia are numerous and can be severe. The combination of increased renal calcium excretion and decreased intestinal calcium reabsorption in response to hypercalcemia results in a new state of equilibrium at a higher serum concentration of calcium. A decrease in glomerular filtration rate, which may be a direct effect of hypercalcemia or secondary to dehydration from vomiting, can exacerbate the hypercalcemia by increasing calcium reabsorption by the kidney. In addition, nephrocalcinosis can occur, ultimately leading to chronic renal failure. Nephrolithiasis, interstitial nephropathy, renal tubular acidosis (RTA), and nephrogenic diabetes insipidus may also accompany prolonged hypercalcemia.

Treatment. Elevation of serum calcium concentrations to greater than 14 mg/dL requires prompt treatment to prevent potentially lethal complications of hypercalcemia. This is even more urgent for hypercalcemia associated with hyperphosphatemia because of the risk of metastatic calcification. Immediate measures are directed toward maximizing renal excretion of calcium. Because these patients are often dehydrated, 0.9% or 0.45% saline solution with 20 to 30 mEq/L of potassium is administered intravenously. Hydration should proceed at rates of 200 to 300 mL/h to promote diuresis. Once adequate hydration is achieved, furosemide may be given at a rate of 20 to 80 mg every 1 to 2 hours. To enhance calcium excretion, the patient should remain in positive fluid balance. Replacement of potassium and magnesium may also be needed.

Long-term treatment depends on the underlying cause of the hypercalcemia. Primary hyperparathyroidism is treated by parathyroidectomy. Secondary or tertiary hyperparathyroidism may be treated by either subtotal parathyroidectomy or total

parathyroidectomy with autonomous parathyroid transplantation. Hypercalcemia secondary to tumor secretion of hormonal mediators may be controlled by extirpation of the tumor. In the presence of metastatic bone disease, inhibition of bone resorption with mithramycin or calcitonin may yield good results. In addition, hypercalcemia due to metastatic breast carcinoma or hematologic malignancies may respond to steroid therapy. Intravenous administration of bisphosphonates has been shown to be extremely effective and safe for treatment of patients with hypercalcemia associated with cancer.⁴⁰ Patients with renal failure benefit from dialysis using a low-calcium dialysate.

Hypocalcemia

Causes. Hypocalcemia secondary to hypoparathyroidism can complicate thyroid or parathyroid surgery by either inadvertent total parathyroidectomy or loss of parathyroid function due to devascularization. This has been reported to occur in as many as 2% to 3% of patients undergoing total thyroidectomy, although this figure appears to be declining. After resection of a parathyroid adenoma, hypocalcemia can occur because of atrophy of the remaining glands. Calcium replacement therapy may be required until the remaining glands resume normal function.

Hypocalcemia can also complicate acute pancreatitis owing to calcium precipitation into the peripancreatic tissues. In addition, pancreatic and small-bowel fistulas may result in loss of calcium-rich fluid. Longstanding vitamin D deficiency secondary to malnutrition, malabsorption, or lack of exposure to sunlight can lead to hypocalcemia. Renal failure can lead to a deficiency in 1,25-dihydroxyvitamin D₃ and result in diminished intestinal absorption of calcium. Severe magnesium deficiency can also lead to hypocalcemia because of suppression of PTH levels.

Clinical Features. Serum calcium levels below 8 mg/dL may be associated with symptoms and signs that are primarily

manifestations of neuromuscular abnormalities. These include muscle cramps, perioral tingling, paresthesia, laryngeal stridor, tetany, seizures, and psychotic behavior. Classic signs of hypocalcemia include hyperactive deep tendon reflexes. Two well-described physical findings occur when a patient becomes hypocalcemic. One of these is Chvostek's sign, which consists of facial muscle spasm when the trunk of the facial nerve is tapped. The other finding is Trousseau's sign, carpal spasms when a blood pressure cuff is inflated to occlude the brachial artery for 3 minutes. This finding indicates latent tetany. ECG changes include a prolonged QT interval caused by prolongation of the ST segment.

Treatment. Asymptomatic hypocalcemia, which may be secondary to low protein or albumin levels with normal ionized calcium levels, need not be treated. Symptomatic hypocalcemia is best treated with intravenous infusion of calcium in the form of calcium gluconate or calcium chloride. Calcium chloride dissociates primarily to the ionized form and is therefore more efficacious in raising ionized calcium levels. Calcium should be administered at a rate not exceeding 50 mg/min (2.5 mEq/min). Prolonged calcium replacement is given orally in the form of calcium lactate, calcium citrate, or calcium carbonate. Vitamin D₃, also known as calcitriol, increases the rate of intestinal absorption and decreases the oral calcium dose requirement.

Magnesium. Total body content of magnesium in the average adult is 2,000 mEq, half of which is confined to bone. Most of the remaining magnesium is distributed in the intracellular space. Less than 1% of total body magnesium is located in the extracellular space, at concentrations of 1.4 to 2 mEq/L (or 1.7 to 2.3 mg/dL). Sixty percent of this magnesium exists in the ionized form, 25% is in the protein-bound state, and the remainder is complexed with nonprotein anionic species.

Approximately 25 mEq/d of magnesium is consumed in the diet, a variable amount of which is absorbed by the small intestine. Magnesium absorption may be influenced by the levels of 1,25-dihydroxyvitamin D₃. Bone stores constitute the other major source of available magnesium, although regulation of magnesium exchange with bone is poorly understood.

Magnesium is excreted primarily by the kidneys. Approximately 40% of the filtered magnesium is reabsorbed in the proximal tubule, predominantly in the ascending limb of Henle. Thus, loop diuretics cause a marked increase in magnesium excretion. Magnesium excretion is also increased by hypomagnesemia, hypercalcemia, metabolic acidosis, and phosphate depletion. Conversely, magnesium excretion is decreased by metabolic alkalosis.

Hypermagnesemia

Causes. Because of the ability of the kidneys to excrete large magnesium loads, hypermagnesemia rarely occurs if renal function is normal. In chronic or acute renal failure, administration of magnesium-containing antacids or laxatives is frequently the cause of hypermagnesemia. Severe burns, crush injuries, and other causes of rhabdomyolysis may lead to high magnesium levels due to the release of magnesium from injured tissues. Severe metabolic acidosis, extracellular volume depletion, and renal insufficiency with creatinine clearances below 30 mL/min may also cause hypermagnesemia.

Clinical Features. Neuromuscular function is depressed by hypermagnesemia because of the inhibition of synaptic acetylcholine release. Loss of deep tendon reflexes can occur with magnesium levels above 8 mg/dL. Paralysis and eventually coma can develop if levels exceed 12 to 18 mg/dL. Hypotension or even cardiac arrest can occur if levels exceed 18 mg/dL.

Treatment. Magnesium-containing medications must be avoided in patients with hypermagnesemia. Calcium antagonizes the effects of magnesium, and infusion of 5 to 10 mEq of

calcium by slow intravenous injection may serve as adequate emergency treatment. Volume expansion, correction of acid-base disturbances, administration of loop diuretics, and hemodialysis may also be used to decrease magnesium levels.

Hypomagnesemia

Causes. Because the kidneys are able to conserve magnesium well in states of magnesium depletion, hypomagnesemia rarely occurs from poor intake alone, although malnutrition is a common cause of hypomagnesemia. Malabsorptive states, especially steatorrhea, can result in significant losses of magnesium. The combination of diminished intake and increased GI losses can lead to hypomagnesemia. Other causes of hypomagnesemia include prolonged periods of intravenous fluid replacement without magnesium replacement and chronic use of loop diuretics. Drugs, such as cyclosporine, aminoglycosides, cisplatin, and insulin, can also produce magnesium depletion. Burns, acute pancreatitis, treatment of diabetic ketoacidosis (DKA), and the diuretic phase of acute renal failure have been associated with the development of hypomagnesemia.

Clinical Features. Magnesium plays an integral role as a cofactor in many enzyme systems and also affects neuromuscular function. Deficiencies in magnesium may present symptoms and signs similar to hypocalcemia. Muscle fasciculations and weakness, tetany, carpopedal spasm, nausea, vomiting, and personality changes may occur. Electrolyte disturbances may also be caused by hypomagnesemia. Hypocalcemia caused by impaired PTH secretion and PTH resistance may develop. Hypokalemia caused by renal potassium wasting may also occur.

Treatment. Magnesium may be administered orally in mild cases of hypomagnesemia, but large oral doses frequently lead to diarrhea. Correction of major deficits is therefore managed by intravenous administration of magnesium sulfate at a dose of 50 to 100 mEq/d. Treatment of patients who have severe symptoms with up to 3 g of magnesium sulfate may be accomplished by bolus intravenous injection followed by an infusion of 1 to 2 mEq/kg per day.

ACID-BASE BALANCE

Definitions

An acid is defined as a chemical that can donate a hydrogen ion (H⁺), for example, HCl and H₂CO₃, and a base is a chemical that can accept a H⁺, for example, OH⁻ and HCO₃⁻. Ampholytes are both acids and bases; an example is H₂PO₄⁻, which can donate a H⁺ to become HPO₄²⁻ but can also accept H⁺ to become H₃PO₄. Because HCl is a strong acid that almost completely dissociates, Cl⁻ is not considered a base. Bases are commonly anions, but neutral substances can also function as bases (e.g., ammonia and creatinine). Some chemicals do not fit the classic definition of an acid, although they retain acidic properties when dissociated in water. For example, when CaCl₂ is dissolved in water, the Ca²⁺ accepts OH⁻ to form Ca(OH)₂. Because [H⁺] × [OH⁻] in water remains constant at 10⁻¹⁴, the consumption of OH⁻ by Ca²⁺ results in increased dissociation of water. Consequently, the concentration of hydrogen ions increases, and CaCl₂ dissolved in water is an acidic solution.

The concentration of hydrogen ions [H⁺] determines the acidity of a solution. The pH is the negative logarithm of [H⁺] expressed in moles per liter (mol/L). The concentration of H⁺ in biologic systems is in the range of nanomoles (10⁻⁹ mol) per liter (nmol/L). When

$$[\text{H}^+] = 40 \text{ nmol/L} = 4 \times 10^{-10} \text{ mol/L}$$

then

$$\text{pH} = -\log[\text{H}^+] = -(-7.4) = 7.4$$

When

$$[\text{H}^+] = 80 \text{ nmol/L} = 8 \times 10^{-10} \text{ mol/L}$$

then

$$\text{pH} = -\log[\text{H}^+] = -(-7.1) = 7.1$$

The degree to which an acid dissociates determines its strength. If an acid, HA, dissociates to H^+ and A^- , then

$$[\text{H}^+] \times [\text{A}^-]/[\text{HA}] = K$$

where K = dissociation constant. The greater the value of K , the greater the ability to dissociate and therefore the greater the strength of the acid. Because most acids have a K value considerably below 1.0,

$$\text{pK} = -\log K$$

Rearranging,

$$[\text{H}^+] = K \times [\text{HA}]/[\text{A}^-]$$

$$-\log[\text{H}^+] = -\log K \times -\log[\text{HA}]/[\text{A}^-]$$

$$\text{pH} = \text{pK} \times \log[\text{A}^-]/[\text{HA}]$$

This is the derivation for the Henderson-Hasselbalch equation.

Buffer Systems

Buffers are chemicals in solution that tend to minimize changes in pH that would otherwise occur after the addition of acid or alkali. If a strong acid is added to the salt of a weak acid and a strong base, the reaction produces another salt and a weak acid:

Thus, the decrease in pH that would have occurred in the absence of NaHCO_3 is minimized. Conversely, if a strong base is added to a weak acid, the base is neutralized:

The elevation in pH after the addition of NaOH is prevented.

One type of buffer is a mixture of a weak acid and its salt, which forms an amount of weak acid or base equivalent to the amount of strong acid or base added to the system. The presence of such buffer systems in the body is crucial in minimizing changes in pH secondary to the daily production of the 70 mEq of acid generated from dietary precursors. There is a relatively narrow range of pH for optimal function of the chemical reactions necessary for cell function.

The principal intracellular buffers are organic phosphates, bicarbonate, and peptides. In addition, hemoglobin functions as a significant buffer in red blood cells. The major extracellular buffer is bicarbonate. An approximation of the total body buffer capacity is 15 mEq/kg. More than half of the total body alkaline buffer content is located outside the ECF and may in large part reside in bone.⁴¹ The buffer pair carbonic acid/bicarbonate ($\text{H}_2\text{CO}_3/\text{HCO}_3^-$) is the focus of the ensuing discussion because it is the primary buffer system of the body and the components of this buffer system are easily measured. Because all body buffer systems are in equilibrium, the state of the $\text{H}_2\text{CO}_3/\text{HCO}_3^-$ system essentially reflects the state of all the body buffers.

From a chemical point of view, the ideal buffer should have a pK that approximates the pH to be preserved. The $\text{H}_2\text{CO}_3/\text{HCO}_3^-$ buffer system has a pK of only 6.1, but this buffer system is efficient because of the presence of large amounts of bicarbonate, the conversion of its acid H_2CO_3 to CO_2 that is rapidly excreted through the lungs, and an inexhaustible supply of CO_2 , although at low concentrations.

The $\text{H}_2\text{CO}_3/\text{HCO}_3^-$ buffer system is defined by the Henderson-Hasselbalch equation:

$$\text{pH} = \text{pK} + \log[\text{HCO}_3^-]/[\text{H}_2\text{CO}_3]$$

In the clinical use of this equation, $[\text{H}_2\text{CO}_3]$ is replaced by $[\text{CO}_2]$ because measurement of the low concentrations of $[\text{H}_2\text{CO}_3]$ present in body fluids is difficult, whereas $[\text{CO}_2]$, which is in equilibrium with $[\text{H}_2\text{CO}_3]$ in a fixed ratio, can be readily measured. Making this substitution, the equation becomes

$$\text{pH} = \text{pK} + \log[\text{HCO}_3^-]/[\text{CO}_2]$$

Because the pK for this buffer system is 6.1,

$$\text{pH} = 6.1 + \log[\text{HCO}_3^-]/[\text{CO}_2]$$

Using normal values for $[\text{HCO}_3^-]$ (24 mEq/L) and $[\text{CO}_2]$ (1.2 mmol/L),

$$\begin{aligned} \text{pH} &= 6.1 + \log 24/1.2 \\ &= 6.1 + \log 20 = 7.4 \end{aligned}$$

A pH of 7.4 is maintained as long as the ratio of $[\text{HCO}_3^-]$ to $[\text{CO}_2]$ remains 20:1. The amount of $[\text{CO}_2]$ in solution is estimated from partial pressure of carbon dioxide (PCO_2) and its solubility coefficient (0.03 in plasma). Making these substitutions,

$$\text{pH} = 6.1 + \log[\text{HCO}_3^-]/(\text{PCO}_2 \times 0.03)$$

Anion Gap

The anion gap is defined as follows:

$$\text{Anion gap} = [\text{Na}^+] - ([\text{Cl}^-] + [\text{HCO}_3^-])$$

Normally, the difference between the serum $[\text{Na}^+]$ and the sum of the chloride and bicarbonate anion concentrations is a reflection of the sum of the serum proteins, sulfate anions, inorganic phosphates, and organic acids present in low concentrations. The anion gap is usually 12 ± 2 mEq/L. Variances from the normal may be caused by a change in unmeasured anions or cations. Calculation of the anion gap may help define both simple and mixed forms of acid–base disturbances. Acidosis associated with a high anion gap is usually secondary to increases in endogenously produced acids (e.g., lactic acidosis or ketoacidosis), decreases in renal excretion of acid, or ingestion of toxins.

Acid–Base Disturbances

- 8 There are four primary acid–base disturbances, each of which are related to changes in either $[\text{HCO}_3^-]$ or PCO_2 . Metabolic acidosis is a decrease in pH as a result of a primary decrease in $[\text{HCO}_3^-]$, whereas metabolic alkalosis is an increase in pH caused by a primary increase in $[\text{HCO}_3^-]$. Respiratory acidosis is a decrease in pH secondary to a primary increase in PCO_2 , and respiratory alkalosis is an increase in pH caused by a primary decrease in PCO_2 . In each of these disorders, compensatory changes occur to minimize changes in the relative ratio of $[\text{HCO}_3^-]$ to PCO_2 and thereby blunt the effect of the primary disturbance on pH (Table 10.11).

Metabolic Acidosis. Three mechanisms result in a decrease in extracellular bicarbonate concentration and metabolic acidosis:

1. Dilutional acidosis. Rapid infusion of an alkali-free solution results in dilution of the bicarbonate concentration.
2. Cellular retention of K^+ in exchange for Na^+ and H^+ . Buffering of the H^+ may result in a transient decrease in extracellular bicarbonate concentration.
3. Decreased body bicarbonate content. This occurs when net loss of bicarbonate exceeds bicarbonate generation.

TABLE 10.11**HCO₃⁻ AND PCO₂ DERANGEMENTS IN PRIMARY AND SECONDARY ACID-BASE DISTURBANCES**

■ DISORDER	■ pH	■ PRIMARY		■ SECONDARY	
		HCO ₃ ⁻	■ PCO ₂	HCO ₃ ⁻	■ PCO ₂
Metabolic acidosis	↓	↓			↓
Metabolic alkalosis	↑	↑			↑
Respiratory acidosis	↓		↑	↑	
Respiratory alkalosis	↑		↓	↓	

The first two mechanisms are relatively infrequent and usually produce only mild, self-limiting metabolic acidosis; however, aggressive “overresuscitation” of surgical or trauma patients with normal saline solution may result in a dilutional acidosis. Most clinically significant metabolic acidosis is related to net loss of bicarbonate, which occurs when consumption due to either loss or titration is greater than bicarbonate generation. Under normal circumstances of ingestion of the average amount of protein in the American diet, approximately 70 mEq of acid is generated daily. The major source of acid production is sulfuric acid from the metabolism of sulfur-containing amino acids. In addition, normal physiologic processes result in the generation of organic acids, the titration of which consumes bicarbonate. Although the resulting organic anions are further metabolized with regeneration of bicarbonate, urinary excretion of some organic anions occurs and results in net loss of bicarbonate.

These sources of acid gain are partially offset by net GI absorption of metabolizable anions, such as citrate, which are metabolized to yield bicarbonate. The remainder of the excess acid is balanced by renal excretion of acid with simultaneous generation of bicarbonate. A decrease in body bicarbonate content may therefore be the result of a primary increase in net acid generation, termed *extrarenal acidosis*, or a primary reduction in renal acid excretion, termed *renal acidosis*.

In extrarenal acidosis, the normal compensatory mechanism is increased renal excretion of acid, usually as ammonia, with generation of bicarbonate. This mechanism is sensitive to decreases in bicarbonate concentration and has the capacity to generate large amounts of bicarbonate.

In contrast, renal acidosis is not as readily compensated because the renal abnormality is the primary mechanism. The level to which serum bicarbonate concentration decreases depends on several factors, including the magnitude of the disparity in acid production and acid excretion as well as its duration. In general, the development of renal acidosis is slow but progressive, whereas the development of extrarenal acidosis is rapid but usually self-limiting. Despite persistent net loss of bicarbonate, extracellular bicarbonate concentration may stabilize at a subnormal level rather than continue to decrease. This may be due to bone buffering, which has the capacity to buffer as much as 28 to 37 mEq/d of acid.

Mechanisms Resulting in Decreased Body Bicarbonate Content

Increased Production of Organic Acids. Increased protein intake and tissue catabolism resulting in greater metabolism of sulfur-containing amino acids can lead to generation of increased amounts of sulfuric acid. With normal kidney function, any decline in serum bicarbonate concentration stimulates renal acid excretion, which can compensate nearly completely for the increase in acid production.

Administration of Exogenous Acid. Ingestion of a sufficient quantity of exogenous acid can exceed renal compensatory

capacity and result in metabolic acidosis. Examples of acids that may be ingested include ammonium chloride, calcium chloride, nitric acid, sulfuric acid, and hydrochloric acid.

Nonrenal Loss of Bicarbonate. Diarrhea, intestinal or pancreatic fistulas, and burns can cause metabolic acidosis secondary to loss of bicarbonate. Urinary diversion with segments of GI tract (ureterosigmoidostomy and ureteroileostomy) can result in loss of bicarbonate with reabsorption of NH₄Cl from the urine. The potential for fistulas to result in metabolic acidosis depends on the concentration of bicarbonate in the fluid and the rate of external drainage. Thus, metabolic acidosis is less common with biliary fistulas than pancreatic fistulas because bicarbonate concentration in bile is usually less than 50 to 60 mEq/L, and the amount of drainage tends to be modest. Bicarbonate concentration in pancreatic juice approaches 150 mEq/L, and the drainage can be profuse.

Organic Acidosis. Organic acidosis describes conditions of acidosis brought about by abnormal endogenous production of specific acid compounds. The two most common types of organic acidosis are *ketoacidosis* and *lactic acidosis*.

Ketoacidosis. Normally, free fatty acids generated from breakdown of triglycerides in adipose tissue are either used as an energy source by tissues such as muscle or carried to the liver, where they are reesterified to triglycerides. Ketoacids are produced by mitochondrial metabolism of free fatty acids to acetyl CoA, with subsequent formation of acetoacetate and β-hydroxybutyrate (redox forms of the same compound). Under normal conditions, a small amount of ketoacidosis is produced. During prolonged starvation, production of ketoacids increases to modest levels, providing an important source of energy to nonhepatic tissues, particularly the brain.

In DKA, the ketoacid production is excessive because of insulin deficiency, which drives ketoacid production by increasing free fatty acid release from adipose tissue, increasing transport of free fatty acids into hepatic mitochondria, promoting conversion of acetyl CoA to ketoacids, and impairing extrahepatic use of ketoacids.⁴² Insulin deficiency also contributes to hyperglycemia by decreasing the metabolism of glucose by extrahepatic tissues and increasing hepatic production of glucose. The resulting osmotic glucose diuresis causes increased renal excretion of sodium and water. Additional losses of sodium and potassium occur as the result of renal excretion of the excess ketoacid anions. Potassium excretion is further enhanced by hyperaldosteronism due to the increased delivery of sodium to the distal tubule that occurs in association with the osmotic diuresis. Despite TBK depletion, serum potassium concentration is often increased in DKA secondary to metabolic acidosis, renal insufficiency, insulin deficiency, and hyperosmolality. These pathophysiologic changes result in the typical clinical presentation, which includes dehydration, polyuria, polydipsia, hyperglycemia,

hyperventilation, and metabolic acidosis with an increased anion gap. Spontaneous decarboxylation of acetoacetate to acetone occurs with excretion of acetone through the lungs, resulting in the characteristic odor described in DKA. Patients may demonstrate impaired mental status or coma in severe cases.

In hyperosmolar, hyperglycemic, and nonketotic coma, moderate acidosis may be observed. The mechanism of the acidosis is not clear. In contrast to the moderate hyperglycemia, averaging 600 mg/dL, seen in DKA, the marked hyperglycemia, averaging 1,200 mg/dL, that occurs in hyperosmolar nonketotic hyperglycemia is not associated with ketoacidosis.

Lactic Acidosis. Lactic acidosis can be characterized as type A (caused by tissue hypoxia) or type B (other causes). Hypoxia impairs the mitochondrial oxidation of the reduced form of nicotinamide adenine dinucleotide (NADH) to NAD, which is necessary for glycolysis. Under these conditions, NADH is oxidized by the reduction of pyruvate, the end product of glucose metabolism in the Embden-Meyerhof pathway, to lactic acid. Thus, generation of lactic acid is the final step of anaerobic glycolysis. Lactic acid is normally produced by muscle, blood elements, intestine, and skin and is used by the liver and kidney. Normal serum lactate concentration is below 2 mEq/L. Lactic acidosis secondary to hypoxia is usually due to increased production of lactate as well as decreased use, and serum lactate concentration is greater than 6 mEq/L.

The most common cause of type B lactic acidosis is ethanol intoxication. Lactic acidosis is caused by increased generation of NADH by the metabolism of alcohol, which interferes with hepatic gluconeogenesis and, therefore, lactate use.

In lactic acidosis, the L-isomer is usually elevated because of the specificity of mammalian lactate dehydrogenase. Various bacteria found in colonic flora are capable of generating large amounts of D-lactic acid. D-Lactic acidosis has been reported in humans only in the presence of short-gut syndrome because the small bowel normally absorbs the dietary substrate for bacterial D-lactic acid production. In addition, the colon must be selectively colonized by bacteria that possess D-lactate dehydrogenase. Typically, the patient has short-gut syndrome, and the acidosis is preceded by food ingestion and is accompanied by characteristic neurologic findings, including mental confusion, slurred speech, staggering gait, and nystagmus. These neurologic manifestations are secondary to bacterial neurotoxins. The acidosis is accompanied by an increased anion gap, but L-lactate and ketone levels are normal. Treatment includes oral antibiotics, recolonization of the colon with non-D-lactate dehydrogenase-forming bacteria, and a low-carbohydrate diet.

Metabolic Acidosis Caused by Drugs and Toxins. Acetylsalicylic acid (aspirin) is rapidly metabolized to salicylic acid and then more slowly to other metabolites that are excreted by the kidney. Ingestion of more than 4 to 6 g/d results in salicylate intoxication with an anion gap metabolic acidosis, as well as renal excretion of unmetabolized salicylic acid. Acidosis increases the toxicity of salicylate by increasing the concentration of its nonionized form, which can achieve high intracellular concentrations. A respiratory alkalosis occurs due to direct stimulation of the respiratory center. Manifestations of salicylate overdose include tinnitus, asterixis, noncardiogenic pulmonary edema, hypotension, vascular collapse, vomiting, seizures, and coma. Treatment consists of alkalinization of the urine to prevent reabsorption of salicylate and hemodialysis in patients with severe neurologic symptoms.

Ethylene glycol, the principal component of antifreeze, is converted by alcohol dehydrogenase to glycoaldehyde, then to glycolic acid with production of one NADH at each step. The acidosis produced by ingestion of ethylene glycol is secondary to accumulation of glycolic acid, although lactate also accumulates because of the production of NADH. Bicarbonate is

not regenerated when the glycolate is further metabolized, so exogenous alkali is required to replace what was titrated. In addition, 3% to 10% of ethylene glycol is converted to oxalic acid, which may result in hypocalcemia and contribute to acute renal failure. Three stages of toxicity are described. CNS dysfunction characterizes the first stage. This is followed by cardiopulmonary failure and finally by oliguric acute renal failure. Treatment includes the administration of ethanol, which has greater affinity for alcohol dehydrogenase and delays the metabolism of ethylene glycol to its toxic metabolites. Treatment also includes hemodialysis or peritoneal dialysis to remove ethylene glycol and glycolate.

Metabolism of methanol by alcohol dehydrogenase results in the formation of formaldehyde and formic acid, both of which are severely toxic. The acidosis is associated with an increase in anion gap secondary to the accumulation of formate. The clinical presentation includes blurred vision or blindness associated with the fundoscopic findings of hyperemic discs and retinal edema, malaise, headache, abdominal pain, vomiting, convulsions, and coma. Treatment includes ethanol infusion to delay the metabolism of methanol by alcohol dehydrogenase, hemodialysis, bicarbonate administration, and intravenous folate to enhance metabolism of formate.

Renal Acidosis: Decreased Net Acid Excretion. The impaired ability of the kidney to excrete acid may be secondary to a decrease in the number of functioning nephrons and is termed *uremic acidosis* or *renal tubular acidosis*. Uremic acidosis, which can occur in both acute and chronic renal failure, is primarily caused by a reduction in ammonia excretion secondary to a reduction in the number of functioning proximal tubular cells. In addition, decreased proximal tubular bicarbonate reabsorption contributes to the development of acidosis. Although the onset of uremic acidosis may be related to declining renal function, its appearance can also be influenced by diet-dependent protein and organic anion ingestion, use of diuretic therapy that stimulates acid excretion, and the extent of tubular versus glomerular injury.

RTA can be classified as distal (type I) or proximal (type II), depending on the primary site of the renal tubular defect leading to acidosis. Distal RTA is characterized by a defect in urinary acidification. It is associated with either hypokalemia or hyperkalemia, depending on the underlying pathophysiologic mechanisms. Proposed mechanisms of distal RTA with hypokalemia include reduced H^+ pump activity and increased tubular permeability with back-leak of secreted H^+ into the tubular cell. In RTA with hyperkalemia, the mechanism is decreased luminal negativity secondary to impaired sodium reabsorption. The major defect in proximal RTA is proximal tubular dysfunction resulting in diminished reabsorption of filtered bicarbonate. Urinary excretion greater than 15% of the filtered load of bicarbonate at normal serum bicarbonate levels is pathognomonic for proximal RTA. Other indicators of proximal tubular dysfunction include glycosuria, aminoaciduria, uricosuria, and phosphaturia.

Clinical Features of Acute Metabolic Acidosis. The major cardiovascular effects of acute metabolic acidosis are peripheral arteriolar dilatation, decreased cardiac contractility, and central venous constriction. These can lead to cardiovascular collapse and pulmonary edema. Catecholamine secretion is stimulated by metabolic acidosis, and in mild cases ($pH > 7.1$), heart rate may be increased. In more severe metabolic acidosis ($pH < 7.1$), the direct effects of acidosis override the catecholamine effects and result in bradycardia and decreased contractility. These depressive effects are magnified by beta-blockers. In addition to these cardiovascular effects, metabolic acidosis can increase oxygen delivery by shifting the oxygen-hemoglobin dissociation curve to the right. In more prolonged metabolic acidosis, this may be partially offset by

decreased production of 2,3-diphosphoglycerate in red blood cells because of a slower rate of glycolysis. Metabolic acidosis can also cause gastric distention, abdominal pain, nausea, and vomiting.

Compensatory Mechanisms

Renal Compensation. The kidney is extremely sensitive to changes in serum bicarbonate concentration and responds by increasing net acid excretion primarily by increasing ammonia excretion. Maximal renal compensation requires 2 to 4 days. In addition, the maximal amount of ammonia excreted during acidosis depends on factors that include the rate of glutamine delivery, effects on glomerular filtration rate by associated conditions such as dehydration, and the type of anion that accompanies the acid because renal acid secretion is stimulated to varying degrees by different anions. Although renal compensation is effective in achieving normal net acid excretion with extrarenal causes of metabolic acid, variable results are seen with renal acidosis. Compensation at times is complete for proximal RTA, whereas compensation usually is incomplete for distal RTA.

Respiratory Compensation. Delay in achieving maximal renal response to an increased acid load causes blood pH to decline, which stimulates hyperventilation. Although effective in promptly raising blood pH, early ventilatory compensation is only partial. Full respiratory compensation can occur in 12 to 24 hours. The magnitude of the decrease in PCO_2 in response to a given degree of metabolic acidosis can be used to determine whether the metabolic acidosis is complicated by coexisting respiratory acidosis or respiratory alkalosis. Although a number of sophisticated mathematic models relating PCO_2 to serum bicarbonate, serum hydrogen ion, and pH have been described, the following is a simple equation that is readily applicable to the clinical situation:

$$dPCO_2 = 1.2 \times d[HCO_3^-] \pm 2.0$$

where $dPCO_2$ = expected decrease in PCO_2 given the measured decrease in serum bicarbonate concentration. For example, if serum bicarbonate is 18, $d[HCO_3^-]$ is 6 ($24 - 18$). The expected $dPCO_2$ is 7.2 ± 2 , or $PCO_2 = 32.8$ ($40 - 7.2$) ± 2 mm Hg. This equation is applicable in mild to moderate metabolic acidosis because pulmonary edema complicating severe metabolic acidosis interferes with maximal ventilatory compensation.

Treatment

Acute Metabolic Acidosis. In surgical and trauma patients, metabolic acidosis is often the result of inadequate tissue perfusion and consequent lactic acidosis. Volume resuscitation alone may be enough to correct this acidosis. Attempts to correct acidosis with exogenous bicarbonate without addressing inadequate tissue perfusion will be unsuccessful. Bicarbonate is best reserved for patients with metabolic acidosis that is either not easily reversible or is so severe that the patient is in danger of cardiovascular collapse. Older patients and those with cardiovascular disease have decreased tolerance for acidosis, and it may be appropriate to administer bicarbonate in these groups before the pH has fallen to critically low levels. The amount of bicarbonate required to increase its serum concentration to any given level cannot be calculated. The goal is to increase the pH to 7.2 to 7.3 by administering one or two ampules of bicarbonate (44.5 to 50 mEq/amp) initially, basing the need for additional bicarbonate on repeated arterial blood gas results. Rapid correction to achieve normal serum bicarbonate concentration may be harmful because organic anions are precursors of bicarbonate, and their eventual metabolism combined with administered bicarbonate may result in metabolic alkalosis. This may be further complicated by persistent hyperventilation in the face of rapidly normalized serum

bicarbonate concentration, resulting in the superimposition of a respiratory alkalosis. In addition, rapid correction of serum bicarbonate concentration may not allow reversal of 2,3-diphosphoglycerate depletion in red blood cells. The resulting leftward shift of the oxygen-hemoglobin dissociation curve may result in tissue hypoxia.

Chronic Acidosis. Distal RTA may be treated with daily doses of alkali to correct acidosis and prevent nephrocalcinosis and nephrolithiasis, and potassium supplementation if hypokalemia is also present. Mild proximal RTA in adults does not require specific therapy. Severe cases ($[HCO_3^-] < 18$) are treated with thiazide diuretics and a low-salt diet aimed to achieve modest volume depletion, which reduces bicarbonate requirement. Children are particularly susceptible to the growth-retarding effects of even mild acidosis, and the threshold for treatment should be low.

Diabetic Ketoacidosis. The correction of both acidosis and hyperglycemia is best achieved by administration of insulin. Metabolism of the anions of the ketoacids begins promptly with insulin therapy and results in the generation of bicarbonate. In addition, insulin inhibits ketone formation and gluconeogenesis and stimulates peripheral uptake of ketones and glucose. An intravenous (IV) dose of 20 IU of regular insulin may be given to initiate therapy, followed by a continuous intravenous infusion of 5 to 10 IU/h. Insulin administration should continue until acidosis resolves. Volume resuscitation requirements in DKA averages 4 to 5 L in the first 24 hours. By alternating liters of normal and half-normal saline, risk of cerebral edema is minimized. Potassium should be administered even in the face of normal or high serum potassium, because hypokalemia develops as acidosis and hyperglycemia are corrected. Unrecognized hypokalemia is a major cause of death from DKA.

Hyperosmolar Nonketotic Acidosis. The key to successful treatment is to seek, recognize, and treat any underlying cause for the hyperosmolar nonketotic hyperglycemia, such as gram-negative sepsis. Hyperglycemia is corrected by the administration of insulin, as described previously. Volume depletion can be more severe than that seen with DKA. Potassium supplementation must be given as well.

Metabolic Alkalosis

Causes. Sustained metabolic alkalosis occurs only if extracellular bicarbonate concentration is increased and renal excretion of excess bicarbonate is inhibited. Extracellular bicarbonate concentration increases can occur through several mechanisms. In surgical patients, loss of HCl is a frequent cause of metabolic alkalosis, most commonly due to vomiting or nasogastric drainage in the face of gastric outlet obstruction. External loss of gastric acid results in a net gain in bicarbonate (generated by equimolar gastric secretion of HCl), which causes the alkalosis. Although the kidney can excrete excess bicarbonate, this must be accompanied by excretion of sodium. Renal excretion of sodium is limited in the face of the volume depletion that also occurs with external losses of gastric secretion. As volume depletion progresses, sodium is conserved in exchange for hydrogen, and urine will become acidic, even in the presence of severe metabolic alkalosis. This phenomenon is referred to as *paradoxical aciduria*.

Increased extracellular bicarbonate concentration can occur with administration of either bicarbonate or precursors of bicarbonate, such as lactate, citrate, or calcium carbonate, or as a result of increased renal production of bicarbonate. Conditions in which acid excretion exceeds endogenous acid production and in which the renal threshold for bicarbonate reabsorption is increased can result in metabolic alkalosis.

Such conditions include moderate potassium depletion, excess mineralocorticoids, and high PCO_2 .

Hypokalemia and cellular exchange of potassium for hydrogen can also lead to metabolic alkalosis. Hypokalemia results in enhanced proximal tubular bicarbonate reabsorption and distal tubular acid excretion. When potassium leaves the cell, it is exchanged for either sodium or hydrogen to maintain electrical neutrality. Loss of potassium from the body then results in a net gain in bicarbonate in the ECF.

Maintenance of elevated extracellular bicarbonate concentration can occur by a number of mechanisms. Volume contraction leads to decreases in renal blood flow and glomerular filtration rate that reduce the filtered load of bicarbonate. This, in addition to increased proximal tubular reabsorption of bicarbonate, maintains high extracellular concentrations of bicarbonate. High PCO_2 causes an increase in renal threshold for bicarbonate secondary to decreased intracellular pH of the renal tubular cell. The net result is increased bicarbonate reabsorption.

Hypercalcemia and low PTH levels both result in increased proximal tubular reabsorption of bicarbonate, which may be enhanced by a decrease in glomerular filtration rate. Renal failure also leads to an inability of the kidney to excrete excess bicarbonate. Diuretics can cause or exacerbate metabolic alkalosis by both causing rapid contraction of intravascular volume and increasing renal excretion of acid. Chloride deficiency is another common factor that maintains an alkalemic state. In some instances of metabolic alkalosis, urinary excretion of chloride is markedly reduced. Reversal of metabolic alkalosis in these cases can be readily achieved by administration of chloride-containing solutions. Although chloride deficiency per se can result in an increased renal threshold for bicarbonate and in increased renal reabsorption of bicarbonate, this apparent association may also be related to volume contraction. Metabolic alkalosis can be divided into chloride-responsive and chloride-resistant types.

Respiratory Compensation. The major compensatory mechanism in metabolic alkalosis is respiratory because the presence of the metabolic alkalosis implicates renal dysfunction in either generating or failing to excrete increased amounts of bicarbonate. Hypoventilation is limited by the development of hypoxemia, which stimulates ventilation, and PCO_2 rarely exceeds 60 mm Hg (Table 10.12). Among the four major types of acid–base disorders, this compensatory mechanism is the least effective. For a given degree of metabolic alkalosis, the following equation can be used to predict the compensatory increase in PCO_2 :

$$d\text{PCO}_2 = 0.7 \times d[\text{HCO}_3^-] \pm 5$$

where $d\text{PCO}_2$ = expected increase in PCO_2 given the measured increase in serum bicarbonate concentration.

Clinical Features. Clinical signs of metabolic alkalosis may not be prominent because the condition usually develops relatively slowly. If acute, CNS manifestations of confusion, obtundation, stupor, and coma may be present as well as tetany and neuromuscular irritability.

Treatment. Correction of the underlying cause is the mainstay of treatment in this disorder. In general, correction of potassium depletion and volume depletion corrects the metabolic alkalosis. Renal excretion of bicarbonate cannot occur in the face of persistent volume depletion. Volume depletion should be corrected with chloride-containing solutions. In patients without intravascular volume deficits, renal excretion of bicarbonate can be enhanced by administration of the carbonic acid anhydrase inhibitor diuretic acetazolamide. If renal excretion of bicarbonate cannot be increased because of underlying renal insufficiency or if the metabolic alkalosis is severe, acid may be administered to titrate directly the excess extracellular bicarbonate. Acids that can be used include ammonium chloride, arginine hydrochloride, lysine hydrochloride, or dilute hydrochloric acid (0.1 N). Partial correction of the alkalosis is the initial goal. A general guide is that 2.2 mEq/kg of acid decreases serum bicarbonate by approximately 5 mEq/L. In the face of renal failure, dialysis may be necessary to remove excess bicarbonate.

Respiratory Alkalosis. Respiratory alkalosis is defined as increased extracellular pH secondary to decreased PCO_2 with hyperventilation. Hyperventilation and the ensuing fall in PCO_2 may be secondary to hypoxia, reflex stimulation from decreased pulmonary compliance, drugs, mechanical ventilation, and other causes.

Hypoxia stimulates ventilation through peripheral chemoreceptors in the carotid and aortic body. Decrease in arterial partial pressure of oxygen (PO_2), rather than in oxygen content, is the main stimulus. Acute drops in arterial PO_2 result in sustained hyperventilation only when the PCO_2 decreases below 60 mm Hg. Although hyperventilation occurs with even slight degrees of hypoxia, the resulting increase in brain pH suppresses the stimulus for hyperventilation unless severe hypoxia is present. In contrast, chronic hypoxia results in hyperventilation even with mildly decreased PCO_2 because brain pH is lowered by metabolic compensation. The two most common causes of hypoxia resulting in respiratory alkalosis are pulmonary disease and exposure to high altitudes.

Compensatory Mechanisms. Tissue buffering is the initial response to a decrease in PCO_2 . Red blood cells provide one third of the buffering. Consumption of bicarbonate results from cellular liberation of H^+ . Although immediate, the

TABLE 10.12

CALCULATIONS FOR ESTIMATING THE COMPENSATORY RESPONSES TO PRIMARY ACID–BASE DISTURBANCES

■ TYPE OF DISORDER	■ COMPENSATION REQUIREMENT	■ TIME
Metabolic acidosis	$d\text{PCO}_2 = d[\text{HCO}_3^-] \times 1.2 \pm 2$	12–24 h
Metabolic alkalosis	$d\text{PCO}_2 = d[\text{HCO}_3^-] \times 0.7 \pm 5$	12–24 h
Acute respiratory acidosis	$d[\text{HCO}_3^-] = d\text{PCO}_2 \times 0.07 \pm 1.5$	Minutes
Chronic respiratory acidosis	$d[\text{HCO}_3^-] = d\text{PCO}_2 \times 0.4 \pm 3$	3–5 d
Acute respiratory alkalosis	$d[\text{HCO}_3^-] = d\text{PCO}_2 \times 0.2 \pm 2.5$	Minutes
Chronic respiratory alkalosis	$d[\text{HCO}_3^-] = d\text{PCO}_2 \times 0.5 \pm 2.5$	2–3 d

magnitude of tissue buffering is slight and can be predicted by the following formula:

$$d[\text{HCO}_3^-] = d\text{PCO}_2 \times 0.2 \pm 2.5$$

Renal compensation is achieved not by increasing excretion of bicarbonate but by decreasing net acid excretion, primarily through reductions in ammonia excretion and increases in organic anion excretion. These organic anions are excreted as sodium and potassium salts. As a result, potassium excretion is increased, resulting in hypokalemia. Complete renal compensation requires 2 or 3 days.

Clinical Features. Chronic respiratory alkalosis is usually asymptomatic because compensatory mechanisms are successful in maintaining pH close to normal. Acute respiratory alkalosis may cause sensations of breathlessness, dizziness, and nervousness and can result in circumoral and extremity paresthesias, altered levels of consciousness, and tetany. These signs are related to decreased cerebral blood flow secondary to the decreased PCO_2 and decreased ionized calcium concentration secondary to the increased blood pH.

Treatment. The underlying stimulus for the hyperventilation should be addressed. The cause of hypoxemia should be determined and corrected. In acute symptomatic respiratory alkalosis, rebreathing or breathing 5% CO_2 temporarily relieves the symptoms. If the condition is secondary to mechanical ventilation, adjustment of tidal volume or respiratory rate should result in resolution of the respiratory alkalosis.

Respiratory Acidosis. Respiratory acidosis, the decrease in extracellular pH from a primary increase in PCO_2 , is due to inadequate ventilation. Causes of hypoventilation include the various causes of CNS depression, as well as impaired thoracic ventilatory mechanics, airway obstruction, and chronic obstructive pulmonary disease. In addition, inappropriate ventilator settings may result in respiratory acidosis in patients on mechanical ventilation.

Compensatory Mechanisms. Increased PCO_2 results in increased H_2CO_3 , which dissociates into H^+ and HCO_3^- . Cel-

lular exchange of Na^+ and K^+ for H^+ allows the reaction to continue in this direction with increased extracellular bicarbonate. This tissue buffering is accomplished within minutes. Persistently elevated PCO_2 also stimulates increased renal acid excretion, primarily the chloride salt of ammonia, and results in increased renal generation of HCO_3^- . Full renal compensation occurs over 3 to 5 days. The following formula describes chronic respiratory acidosis:

$$d[\text{HCO}_3^-] = d\text{PCO}_2 \times 0.4 \pm 3$$

Clinical Features. The magnitude of clinical manifestations depends on the chronicity and rate of development of respiratory acidosis. Acute increases in PCO_2 result in cerebral acidosis, manifested by drowsiness, restlessness, and tremor, as well as stupor or coma in more severe cases. Cerebral vasculature dilation occurs in response to acidosis, resulting in increased cerebral blood flow. This may, in turn, result in increased intracranial blood pressure, headache, and papilledema. Systemic acidosis results in peripheral vasodilatation, depressed cardiac contractility, and insensitivity to catecholamines.

Treatment. Treatment should be directed to the underlying cause of hypoventilation. Endotracheal intubation to achieve adequate ventilation is key to the treatment of acute respiratory acidosis of any cause. The treatment of chronic, compensated respiratory acidosis may be complicated by the accompanying hypoxemia. In chronic hypercapnia, the central chemoreceptors may be insensitive, and the accompanying hypoxemia may supply the main respiratory drive through stimulation of peripheral chemoreceptors. In such patients, complete correction of the hypoxemia may further suppress respiration and worsen the respiratory acidosis. In addition, PCO_2 should not be normalized rapidly. Reequilibration of cerebral bicarbonate concentration lags behind systemic changes. Thus, even if PCO_2 is normal, cellular and cerebral metabolic alkalosis may develop.

Mixed Acid-Base Disorders. Combinations of two or more of the four primary acid-base disorders may occur and should be suspected when blood pH approaches normal despite abnormal PCO_2 and $[\text{HCO}_3^-]$, or when compensatory changes appear to be either excessive or inadequate (Fig. 10.8).

FIGURE 10.8. Acid-base nomogram. Shown are the 95% confidence limits of the normal respiratory and metabolic compensations for primary acid-base disturbances. (Reproduced with permission from Cogan MG, Rector FC Jr. Acid-base disturbances. In: Brenner BM, Rector FC Jr, eds. *The Kidney*. Philadelphia, PA: WB Saunders; 1986:473.)

Familiarity with the acid–base disorders associated with various clinical situations and the expectation of mixed abnormalities allows appropriate interpretation of arterial blood gases and serum electrolyte determinations. A summary of the calculations for estimating the compensatory responses and timing of these responses is presented in Table 10.12.⁴³

CHAPTER 11 ■ BURNS

NICOLE GIBRAN

KEY POINTS

- 1 Burns should be triaged to a burn center with a multidisciplinary care team according to American Burn Association criteria.
- 2 Burn depth evolves over 72 hours, making early surgical decisions difficult.
- 3 Inhalation injury constitutes three types of injury—upper airway thermal burns, chemical pneumonitis, and carbon monoxide toxicity—and with a thermal injury is associated with increased mortality.
- 4 Fluid resuscitation during the first 24 to 48 hours after injury must be titrated to urine output (30 mL/h for adults; 1 to 1.5 mL/kg per hour for children <20 kg) and mean arterial blood pressure (≥ 60 mm Hg).
- 5 Prophylactic systemic antibiotics other than tetanus prophylaxis are contraindicated.
- 6 Of all interventions in the care of patients with thermal injuries, early excision and grafting has had the most significant impact on burn patient survival.
- 7 Patients should be treated for background pain, breakthrough pain, and procedural pain as well as for anxiety.
- 8 Rehabilitation should start at admission with active range of motion if possible and passive range of motion with splinting if the patient is not able to participate.
- 9 Toxic epidermal necrosis is best treated at a burn center with biological dressing to allow the underlying skin to heal; systemic steroids are associated with worse mortality rates.
- 10 Necrotizing fasciitis should be highly suspected if a patient has signs of sepsis together with marked induration and edema with skin blistering/sloughing and a white blood cell count greater than 20,000 and hyponatremia ($\text{Na} < 135$).

Comprehensive care of the patient with thermal injuries involves sophisticated surgical decision making, critical care management, rehabilitation, and psychosocial interventions. With early excision and grafting and better critical care management, survival rates have improved markedly since the mid-1970s. Therefore, in the 21st century, clinical goals must focus on optimizing outcomes and returning patients to their premorbid level of function. This chapter presents a management philosophy that correlates increasing understanding of burn pathophysiology with optimal clinical management of patients with thermal injuries and promotes a systematic multidisciplinary approach.

MANAGEMENT PHILOSOPHY

Whereas the coordinated care provided by a burn center may primarily benefit patients with complicated life-threatening large burn injuries, excellent multidisciplinary management of smaller burns bears long-term beneficial impact on patient outcome—both aesthetic and functional. The focused systematic approach of an organized burn center allows for early surgical excision and closure of burn wounds, critical care support, patient and family psychosocial support, patient and family education, continuous long-term rehabilitation, reentry into society, and reconstructive surgical needs.¹ Therefore, patients with burns that meet American Burn Association criteria (Table 11.1) for transfer to a burn center soon after initial assessment are likely to benefit from a multidisciplinary specialized burn care plan. (Guidelines for the Operations of Burn Centers [pp. 79–86], Resources for Optimal Care of the Injured Patient: 2006, Committee on Trauma, American College of Surgeons.)

With modern burn care, survival with an excellent quality of life should be expected for most patients with severe burns. Predicting mortality is difficult in burned patients. There remain no reliable formulas for predicting burn survival in spite of the easily remembered “Age + % total body surface area burn = mortality” formula.² In one statistical evaluation, age over 60 years, full-thickness burn size over 40% total body surface area

(TBSA), and the presence of inhalation injury were found to be important prognostic factors.³ One retrospective study of patients with burns over 65% TBSA suggested that the nontangible presence of family and friends at the bedside was more common in survivors than in patients who died.⁴ Experienced burn surgeons report that they may limit resuscitation based on burn size, availability of donor sites, patient age, comorbidity, and inhalation injury; however, this approach to providing comfort care for devastating injuries must be carefully and thoroughly discussed by knowledgeable burn care providers with consideration for patient values and interests (unpublished data).

Successful burn patient outcomes require a well-organized care plan. The national trend to include family members in all aspects of patient treatment including access to trauma and intensive care unit (ICU) rooms^{5,6} is a natural extension from the multidisciplinary care teams supported by the burn community.⁷ Deciding whether outpatient management is appropriate for a patient with small burns (1% to 5% TBSA) that do not involve joints or vital structures or when to discharge a patient with a large burn requires clear communication with the patient and family.

Outpatient management often fails because insufficient teaching in a busy emergency room leads to inadequate pain control, wound infection, and limited movement. Indications for burn patient hospitalization include wound care needs, physical therapy, and pain management. In spite of major issues regarding access to care and hospital overcrowding, even patients with minor burns benefit from a short hospital stay immediately after the injury and before swelling, infection, or functional limitations hinder long-term recovery. A burn specialty therapist can educate the patient about expected range-of-motion exercises and activity programs; early understanding of importance of exercise can prevent range-of-motion limitation and subsequent swelling that often leads to infection and uncontrollable pain. Pain, including background pain (pain experienced with ordinary daily activities), breakthrough pain (the pain that occurs in spite of scheduled pain medicines), and procedural pain (pain experienced during wound care or intensive therapy sessions), and anxiety should be carefully

TABLE 11.1**AMERICAN BURN ASSOCIATION CRITERIA FOR PATIENT TRANSFER TO A BURN CENTER**

Burn injuries that should be referred to a burn center include the following:

1. Partial-thickness burns >10% total body surface area (TBSA)
2. Burns that involve the face, hands, feet, genitalia, perineum, or major joints
3. Third-degree burns in any age group
4. Electrical burns, including lightning injury
5. Chemical burns
6. Inhalation injury
7. Burn injury in patients with preexisting medical disorders that could complicate management, prolong recovery, or affect mortality
8. Patients with burns and concomitant trauma (such as fractures) in which the burn injury poses the greatest risk of morbidity or mortality.
If the trauma poses the greater immediate risk, the patient may be initially stabilized in a trauma center before being transferred to a burn center.
Physician judgment will be necessary in such situations and should be in concert with the regional medical control plan and triage protocols.
9. Burned children in hospitals without qualified personnel or equipment for the care of children
10. Burn injury in patients who will require special social, emotional, or long-term rehabilitative intervention

assessed. Analgesic and anxiolytic medication should be titrated to individual levels. Inadequate pain management frequently leads to hospital readmission. Pain levels may increase as epithelial buds emerge in a healing partial-thickness burn and new-onset stinging pain may indicate a superficial wound infection. Change in symptoms indicates that the burn should be evaluated for signs of infection, including wound erythema or breakdown of a previously healed wound.

Simple wound care is a key to successful transition to outpatient management. For all but major burns greater than 40% TBSA, once-daily dressing changes are adequate. Burns are effectively washed during a daily shower or bath with tap water and nonperfumed soap. Using a soapy washcloth to wipe the topical ointment bacteria that have accumulated over the past day from the wound provides adequate wound care; there is no need to scrub the wound to débride superficial exudates. Intact blisters provide a useful protective biologic wound dressing unless they limit mobility, in which case blisters should be incised, débrided, and covered with a topical antimicrobial dressing that allows full range of motion.

A common misconception is that joint immobilization promotes burn wound healing. In reality, extremity immobilization leads to swelling, which worsens tissue injury, exacerbates pain, and increases the risk of wound infection. Patients with hand burns must learn exercises to maintain range of motion and patients with foot burns must ambulate without assistive devices, so that muscle contraction facilitates lymphatic drainage of the extremity. Patients must elevate burned extremities when they are not actively exercising to reduce swelling. Many burn patients underestimate the time and commitment they must dedicate to physical therapy for optimal functional recovery.

EPIDEMIOLOGY

Because burns are an unreported disease, the annual incidence of thermal injuries is unknown. However, extrapolation from

TABLE 11.2**RISK FACTORS FOR BURN INJURIES**

Alcohol and drugs
Age (very young/very old)
Smoking
Socioeconomic status
Occupation
Violence
Epilepsy

2003 Centers for Disease Control and Prevention (CDC) data (<http://www.cdc.gov/ncipc/>) on fire-related injuries suggests that approximately 1 million burn injuries occur annually in the United States. Fire-related deaths in the United States in 2003 are estimated to be 3,700 (1.3 deaths per 100,000); this compares to 322,000 (5.2 deaths per 100,000) worldwide deaths (http://www.who.int/violence_injury_prevention).

In general, burn injuries affect vulnerable populations (Table 11.2): the very young and old, the impaired, and those in lower socioeconomic groups. Workplace injuries comprise a significant component of burn injuries among young adults. Structural fires historically were associated with large numbers of patients with large burns. However, introduction of smoke detectors has dramatically reduced the numbers of these burns except in cases where the alarms are tampered with or when the inhabitants are cognitively or physically impaired. As with other trauma, alcohol and drugs are often implicated in the epidemiology of burn injuries. Suggestion of a nonaccidental injury or potential neglect mandates admission for full evaluation of the home situation; if the history and the burn distribution are consistent with abuse, the patient must be referred to protective services. Likewise, suggestion of a self-induced burn injury should trigger admission for psychological evaluation; the presence of multiple small cigarette burns in various phases of healing is an absolute indication for admission to the hospital for psychological evaluation, even though the burns themselves may be easily cared for at home with bandages. Patients with language barriers may also benefit from a brief hospital admission to be sure they understand the treatment plan. Underinsured and homeless patients may not have the resources to care for a wound outside the hospital and should be admitted for initial wound care and comprehensive discharge planning.

In spite of regulations established after mass burn casualties such as the Coconut Grove Fire in Boston in 1942, the risk of burn mass casualties in public places continues to be a public concern as evidenced in the 2002 Rhode Island nightclub fire that killed 100 people and injured approximately 200 others. Extensive legislative efforts and public outreach programs have decreased the incidence of many nonaccidental burn injuries. Examples including state mandates that hot water heaters in multidwelling facilities be set at 120°F have led to a decreased incidence of nonaccidental hot water injuries.⁸ Inconsistent application of these laws across states remains a problem. Smoke detectors and annual drives to change the batteries have decreased serious injuries in house fires. Federal requirements that children's sleepwear be fire retardant, implemented in 1972, represented a transiently successful national burn prevention program that died in 1996 when Congress reversed regulations. Abuse and neglect continue to impact pediatric patients and require ongoing public awareness campaigns.⁹ One recent national legislative lobbying effort has been the implementation of laws requiring that cigarettes have reduced propensity to ignite furniture or mattresses by using less-dense tobacco, less-porous paper, a smaller diameter, a filter tip, and no added citrates to the paper.¹⁰ As of December

2008, 37 states and the District of Columbia have passed legislation requiring that cigarettes sold in those states meet fire-safe requirements (www.firesafecigarettes.org).

BIOLOGY OF SKIN

Two distinct layers, the epidermis and the dermis, comprise the skin. The outer epidermis acts as the barrier against the environment and protects against infection, toxin absorption, ultraviolet light exposure, fluid evaporation, and thermal regulation. It has five progressively differentiated layers of keratinocytes, leading to the outermost nonviable and relatively impermeable stratum corneum, which provides the barrier mechanism that protects the underlying tissues. In contrast, the dermis is a complicated cellular and extracellular layer that contributes cutaneous durability and elasticity. The fibroblast, the principal cell of the dermis, synthesizes and degrades mesenchymal proteins. Since there is no single fibroblast marker, it is not entirely clear that the spindle-shaped cells that populate the dermis constitute a single cell type. The epidermis and dermis both harbor bone marrow–derived inflammatory cells that contribute to cutaneous inflammatory responses. Dermal connective tissue projections known as dermal papillae interdigitate with epidermal projections known as rete ridges to create the dermal-epidermal junction. Here, the basement membrane,

a complex extracellular matrix layer made up of structural proteins that anchor the basal keratinocytes to the papillary dermis, separates the two cutaneous layers.

BURN PATHOPHYSIOLOGY

Jackson's 1953 classification of burn wound depth remains a basis for our understanding of the pathophysiology of cutaneous thermal injury.¹¹ He described three zones of tissue injury following burn injury (Fig. 11.1A, B). The central, most severely damaged area is the zone of coagulation because the tissue is coagulated or necrotic and irreparably injured; this region represents a full-thickness burn (third degree) (Fig. 11.1C) that will not heal and must be débrided and grafted. Surrounding the zone of coagulation is a zone of stasis, characterized by vasoconstriction and ischemia. With careful wound management, this partial-thickness burn (second degree) (Fig. 11.1D) can convert to a shallower wound; however, edema, infection, or poor perfusion increases the risk that the injured tissue will convert to a deeper burn that will require excision and grafting. The outermost area of a burn is the zone of hyperemia or superficial partial-thickness burn (Fig. 11.1D), which usually heals quickly without scarring. Superficial burns such as sunburns are often referred to as first-degree burns and are not included in burn size calculations.

FIGURE 11.1. Zone of injury correlates with burn depth. **A, B:** The central zone of coagulation (*a*) represents a full-thickness burn (as shown in **C**); the surrounding zone of stasis (*b*) represents a partial-thickness burn (as shown in **D**) that may extend into the reticular dermis (deep partial thickness) or the papillary dermis (superficial partial thickness). The peripheral zone of hyperemia (*c*) correlates with a superficial or first-degree burn and might be similar to a sunburn.

Tissue repair represents a continuum that begins immediately following injury. An initial hemostatic response involves coagulation and microvasculature constriction. The extrinsic and intrinsic coagulation pathways also provide provisional matrix scaffolding for subsequent cellular migration into the wound bed. Tissue factor activation of the coagulation cascade leads to cleavage of fibrinogen to fibrin, which serves as both clot matrix and wound bed matrix. Wound inflammatory cells generate plasmin for clot resolution, a process tightly regulated by plasminogen activator inhibitors to ensure that the clot does not resolve too rapidly. Interestingly, animal studies suggest that exogenous tissue plasminogen activator promotes conversion of the zone of stasis in an acute burn wound to a zone of hyperemia.¹²

The well-recognized vasodilatation and capillary leak associated with the resuscitative phase of a burn injury follow the early transient vascular constriction. Vascular permeability contributes to inflammatory cell migration into the wound bed but also causes extravascular leak, which complicates overall patient outcome by causing pulmonary edema, compartment syndrome, and conversion of burns to a deeper injury. Many inflammatory cytokines contribute to this response. In addition to the many interleukins and prostaglandins, sensory nerve-derived neuropeptides induce histamine release by mast cells,¹³ cytokine and adhesion molecule upregulation by keratinocytes and endothelial cells, inflammatory cell chemotaxis, and fibroblast proliferation.¹⁴ Serotonin, histamine, bradykinin, and the arachidonic acid metabolites prolong vasodilatation and capillary permeability.¹⁵

Resident cutaneous cells may be the most important contributors to cutaneous inflammation. *Skin-associated lymphoid tissue* includes bone marrow–derived cells, such as Langerhans cells and dermal dendrocytes, and keratinocytes and microvascular endothelial cells.¹⁶ Keratinocytes and dermal microvascu-

lar cells synthesize cytokines, including interleukins,^{17–21} monocyte chemoattractant protein-1,²² and tumor necrosis factor.^{23,24} Before margination into the wound bed, neutrophils adhere to endothelial cell adhesion molecules and plug the capillaries, thereby inducing further cytokine release and potential tissue ischemia. In burn wounds, the zone of stasis represents ischemic tissue that may convert to a zone of coagulation with neutrophil-mediated reperfusion injury. Whereas inhibition of the neutrophil-endothelial adherence in deep dermal rabbit contact burns speeds healing,²⁵ these studies have not been verified in human burn patients.

Granulation tissue, with its capillary arcades, is well-recognized clinical evidence that a wound is healthy and is ready for closure. However, normal excisional wound closure occurs with angioinhibition,^{26,27} suggesting that secondary wound repair may not require angiogenesis. Skin grafts and tissue flaps do require angiogenesis for engraftment. Whereas delivery of oxygen and nutrients to a skin graft by imbibition—or diffusion—suffices for a few days, skin graft take requires neovascularization, which occurs by inosculation, the linkage between existent capillaries in the graft and in the wound bed. Excessive wound granulation actually hinders burn wound healing as it prevents migration of the epithelial tongue; many burn surgeons debride the granulation tissue in a healing burn before applying a skin graft to maximize graft take because of the associated bacterial contamination and exuberant inflammatory response. Excessive granulation tissue has been associated with increased hypertrophic scar formation in the healed wound.^{28,29}

An epithelialized burn equals a healed burn. Full-thickness wounds heal from the wound edges (Fig. 11.2A), but an advancing epithelial tongue can migrate for approximately 1 cm before it stops migrating and heaps up at the wound edge. In contrast, partial-thickness wounds heal from epidermal

FIGURE 11.2. A: Epithelialization of a full-thickness wound occurs from the wound edge. B: Partial-thickness wounds heal from the epidermal appendages throughout the wound bed; the arrows depict “buds” of epithelium at each of the appendages. The arrowhead shows the silver sulfadiazine that should be gently washed daily from the wound surface. C: Repigmentation of healed wounds occurs as melanocytes migrate from the epidermal appendages across the wound bed. Skin color in a healed wound is difficult to predict. Exposure to ultraviolet radiation can permanently increase the pigmentation. Bleaching agents are discouraged because of the risk of further tissue damage.

appendages (i.e., hair follicles, sweat glands, and sebaceous glands) in the wound bed (Fig. 11.2B). Whereas completion of this process by no means represents the end of burn wound healing, epithelialization restores the three protective barrier functions of the outer layer of the skin: fluid maintenance, temperature regulation, and prevention of microbial or toxin invasion. Epithelialization may also represent an essential transition in the wound inflammatory state. Growing evidence suggests that epidermal–dermal interactions regulate cutaneous morphogenetic processes such as fetal skin development and wound repair.³⁰ Just as the epidermis responds to mesenchyme-derived mediators,³¹ activated keratinocytes in the advancing epidermal tongue may secrete cytokines and growth factors to promote dermal inflammation.^{32,33} Once cell–cell contact is achieved with complete wound epithelialization, release of the inflammatory mediators may stop. Evidence for epidermal influence on dermal inflammatory responses includes clinical observations that partial-thickness wound coverage with viable allograft eliminates granulation tissue formation and promotes healing.³⁴ Because it takes time for a mature basement membrane to develop, epithelialized wounds undergo epidermolysis (blistering) until the anchoring structures mature.

Whereas clinicians consider an epithelialized wound to be “healed,” long-term dermal and subcutaneous fibrogenesis may be the most critical determinants of long-term wound appearance and cutaneous tensile strength. Deposition of fibrin, thrombin, fibronectin, and vitronectin into the site of injury promotes cellular migration and proliferation for angiogenesis and fibrogenesis. As fibroblasts migrate into the wound from the margins, they synthesize collagen. The result is deposition of collagen III and subsequently collagen I in a dense mat that is characteristic of dermal scar. As collagen I fibrils are cross-linked into cables, dermal breaking strength increases but never meets that of uninjured skin. Matrix remodeling begins with fibrin clot dissolution and ends with a mature wound 12 to 24 months later. Matrix metalloproteinases (MMPs) have been implicated in keratinocyte migration,³⁵ angiogenesis,³⁶ and dermal matrix remodeling.^{37,38} Expression levels of MMPs appear to be decreased in hypertrophic scars.³⁹

Contraction, resulting from centrifugal forces in the center of the wound, constitutes an important wound closure mechanism. Myofibroblasts, specialized fibroblasts characterized by intracellular smooth muscle actin filaments,²⁹ may contribute to this means of closure. A pathologic extension of wound contraction over joints is a contracture—a debilitating scarring process that compromises return to function in many patients with large burns. Constant attention to stretching, exercising, and splinting can minimize contracture development, but surgical release of the tight bands may be necessary to restore normal function of the extremities, neck, or mouth.

Just as the dermis undergoes changes, the epidermis also evolves after injury. Melanocytes migrate from the wound edge and from epidermal appendages soon after the epithelial cells (Fig. 11.2C). Patients must be informed that pigmentation in healed burn wounds can be unpredictable and may result in either increased or decreased melanin. Most clinicians advise patients that exposure to ultraviolet rays exacerbates pigmentation changes in the wound. Use of topical bleaching agents should also be discouraged. Patients with healing partial-thickness wounds complain of pruritus. Hypertrophic scars, which are classically very pruritic, have increased numbers of sensory nerves compared to normal scars and uninjured skin.^{40,41}

tion, inadequate tissue perfusion, and, ultimately, risk of multi-organ dysfunction. Therefore, patients with large burns require continuous intravenous replacement to compensate for the capillary leak. The leak associated with a burn larger than 30% TBSA (or smaller if there is concomitant inhalation injury) can cause clinically significant interstitial edema in soft tissues including muscle compartments, the lungs, and the abdomen. The potential morbidity from the edema includes compartment syndrome in injured and noninjured extremities, abdominal compartment syndrome, and pulmonary edema leading to development of adult respiratory distress syndrome. Careful attention to fluid status of the acutely injured burn patient can avoid resuscitation failures including inadequate and excessive resuscitation.

INITIAL EVALUATION

A burn patient is a trauma patient and should be addressed with the same organized approach to serious injuries that begins with the primary survey to assess airway, breathing, and circulation. A systematic early comprehensive secondary survey is mandatory, especially for burn patients with associated trauma such as seen in motor vehicle collisions. Evidence suggests that even a small burn injury significantly worsens prognosis in patients with multiple injuries and high injury severity scores.⁴² Therefore, close coordination between the trauma and burn teams is indicated, especially during the resuscitative phase of response to injury.

Since workup of a trauma patient is covered extensively in Chapter 17, this section focuses on elements of the workup relevant to evaluation of the burn component of the injuries. Expedient transfer of a critically burned patient to a burn ICU is essential to avoid hypothermia and resuscitation complications; this mandates rapid evaluation in the emergency department. Table 11.3 is an example of a transfer protocol that outlines initial management of the burn patient prior to transfer to a burn center.

A crucial part of the initial evaluation of the extent of burn injury is estimation of the size and depth of the burn. This is the basis for subsequent fluid resuscitation and care plans. Because the zones of injury in a burn wound evolve for up to 72 hours (see earlier discussion on the zones of injury), burn depth determination at the initial examination can be erroneous. Although numerous burn depth indicators have been investigated, including laser Doppler flow meters, intravenous fluorescein, burn wound biopsy, thermography, light reflectance, magnetic resonance imaging, and intravenous dyes,^{43–45} no technology has been more accurate than an experienced burn surgeon. Therefore, many indeterminate burns must be in a “wait and watch” plan to determine whether the burn will heal within 3 weeks or whether excision and grafting will be necessary to close the wound.

Two simple formulas exist to estimate burn size. The rule of nines (Fig. 11.3) provides an anatomic estimate in which each arm is considered to be 9% TBSA, each leg 18%, the anterior trunk 18%, the posterior trunk 18%, and the head 9%; this method underestimates head size in children. Another easy method involves using the patient’s full palm, including digits, to represent 1% TBSA. First-degree burns should not be included in the calculation of burned areas. Soot should be gently cleaned from the patient since it often misleads an unfamiliar evaluator and erroneously increases the estimated burn size.

Initial assessment of the burn patient requires few laboratory or radiologic studies. Patients with a history of exposure to noxious fumes should have partial pressure of arterial oxygen (PaO₂), partial pressure of arterial carbon dioxide (PaCO₂), pH, and carboxyhemoglobin (CO) percentage determined. Patients with isolated burns without other injuries rarely need blood products during the resuscitative phase of

SYSTEMIC RESPONSE TO BURN INJURY

Cutaneous inflammatory cells release mediators from the injured tissue to drive the systemic response to cutaneous thermal injury, leading to accelerated intravascular volume deple-

TABLE 11.3**UNIVERSITY OF WASHINGTON BURN CENTER TRANSFER STABILIZATION PROTOCOL**

1. Remove source of heat.
 - Remove clothing that is burned, covered with chemicals, or constrictive.
2. Intubate patients for:
 - Loss of consciousness, increasing stridor or hoarseness, evidence of posterior pharyngeal burns, or burns exceeding 60% total body surface area (TBSA).
3. Initiate fluid resuscitation.
 - Estimate the burn size based on the rule of nines or based on patient palm size (1% TBSA) to calculate the resuscitation fluid volume (Fig. 11.3).
 - Administer lactated Ringer solution at 3 mL/kg/% TBSA burn.
 - For children who weigh <20 kg, also administer D₅ ½NS at maintenance IV rate.
 - a. Except for maintenance fluids in children, dextrose solutions cause osmotic diuresis and confuse assessment of resuscitation.
 - Unless mean arterial blood pressure is <60 mm Hg, IV fluid boluses are not necessary for burn resuscitation.
4. Insert nasogastric tube in intubated patients and patients with burns ≥20% TBSA.
 - Enteral tube feedings should be started if the patient will not be transported to a burn center within 12 h.
 - If feeding is contraindicated, a proton pump inhibitor should be started.
5. Insert Foley catheter in patients with burns >20% TBSA to assess urine output as a measure of resuscitation.
 - Adequate urine output is 30 mL/h in adults and 1.5 mL/kg/h in a child weighing <20 kg.
 - Observe urine for burgundy color (seen with massive injuries or electrical burns). The high incidence of renal failure associated with myoglobinemia from these injuries warrants prompt and aggressive intervention.
 - If the urine is red or brown, consult burn center staff for fluid management.
6. Escharotomy
 - If transfer will occur within 12 h of injury, escharotomies are rarely needed.
 - Burned extremities should be elevated.
7. Medications
 - A tetanus shot should be given on admission to the emergency department.
 - Antibiotics are NOT indicated for acute burn management.
 - Short-acting pain and anxiety medication may be titrated in small doses.
8. Wound care
 - Débridement and application of topical antimicrobials are usually unnecessary.
 - Transport patient in dry sheets and blankets, keeping patient warm.
 - Avoid hypothermia.
9. Special considerations for chemical burns
 - Remove ALL clothing.
 - Brush powered chemicals off wound: flush burns for a minimum of 30 min with running water. Be careful to protect yourself.
 - Irrigate burned eyes with a gentle stream of saline. Follow with an ophthalmology consult if transport is not imminent.
10. Special considerations for electrical injuries
 - Elevate burned extremities above the level of the heart on pillows.
 - Monitor distal pulses and neurologic examination.
 - Maintain urine output >100 mL/h if myoglobinuria present

FIGURE 11.3. Estimating burn size accurately is essential for care of the burn patient. The rule of nines provides a simple algorithm for calculating the burned surface area.

their care but a routine blood sample can be sent to the blood bank as a type and screen. Routine hematology and chemistry profiles have limited use, but baseline electrolyte levels and renal function (blood urea nitrogen [BUN], creatinine), hematocrit, white blood cell count, and platelet count should be established. The efficacy of following laboratory values such as base deficits and lactic acid levels has not been established in burn patients. Urinalysis may be helpful to diagnose myoglobinuria in patients with electrical injuries or deep thermal burns, but if the urine appears clear, treatment is not warranted. Need for radiographic assessments must be based on mechanism of injury, but a baseline chest radiograph is sufficient for an isolated burn without other evidence of trauma.

AIRWAY ASSESSMENT AND MANAGEMENT

- 3 Airway assessment and management in the burn patient must include diagnosis of an inhalation injury since this significantly increases morbidity and mortality of patients with thermal injuries. Diagnosis of an inhalation injury should be considered for any patient involved in a closed space fire, but inhalation injury may also occur in a patient who is injured outdoors; a patient who throws gasoline onto a bonfire can inhale the petroleum fumes or liquid and sustain a significant chemical pneumonitis. Clues in the physical examination include singed nasal hairs and facial burns, but these do not in themselves indicate the presence of an inhalation injury. The decision to intubate should be based on respiratory and mental status;

TABLE 11.4
CARBOXYHEMOGLOBIN LEVEL CORRELATIONS WITH PATIENT SYMPTOMS

CARBOXYHEMOGLOBIN LEVEL (%)	SYMPTOMS
<10	None
15–25	Nausea, headache
30–40	Confusion, stupor, weakness
40–60	Coma
>60	Death

hoarseness, wheezing, or stridor suggests pharyngeal swelling and indicates intubation. In patients with these signs and symptoms, direct laryngoscopy should be performed to confirm posterior pharyngeal mucosal sloughing or carbonaceous sputum coming up through the vocal cords. Patients with large burns who will receive massive intravenous resuscitation volumes should be intubated for airway protection as swelling progresses. With swelling or with face burns, securing the endotracheal tube can be a challenge and requires that an umbilical tie be used rather than tape; arch bars allow the tube to be wired in place, which facilitates wound care and minimizes pressure points. Nasotracheal intubation should be avoided if possible because of the risks of sinusitis and erosion of the nasal columella, especially if the nose is burned. Intubated patients with inhalation injuries should have the head of their bed elevated to 45 degrees to reduce swelling and to prevent aspiration and ventilator-associated pneumonia.

Inhalation Injury

Inhalation injury complicates approximately one third of all major burns. Whereas isolated inhalation injuries do not result in high mortality, they significantly increase mortality in patients with cutaneous burns.^{46–51} Presumably, the combined injuries lead to recurrent or persistent bacteremia from the burn wound that potentiates the pulmonary injury. Unfortunately, no reliable long-term outcome data exist about late sequelae related to inhalation injury.

Carbon Monoxide Poisoning. Carbon monoxide (CO) toxicity is the most commonly diagnosed form of inhalation injury since clinical signs and symptoms correlate with arterial carboxyhemoglobin levels (Table 11.4).

CO toxicity is easily treated with 100% inhaled oxygen, which rapidly accelerates CO dissociation from hemoglobin (Table 11.5). Hyperbaric oxygen treatment has been proposed

TABLE 11.5
CARBON MONOXIDE–HEMOGLOBIN HALF-LIFE WITH OXYGEN TREATMENT

CARBOXYHEMOGLOBIN HALF-LIFE	TREATMENT MODALITY
4 h	Room air
45–60 min	100% oxygen
20 min	100% oxygen at 2 atm (hyperbaric oxygen [HBO])

as an expeditious way to reduce carboxyhemoglobin levels, but data are controversial.^{52–54} Hyperbaric treatment may be appropriate in the patient who has isolated CO toxicity with impaired neurologic status and a markedly elevated carboxyhemoglobin level ($\geq 25\%$).

However, the risks for a burn patient ($\geq 10\%$ TBSA) undergoing resuscitation in an isolated hyperbaric chamber may be too significant. Reported life-threatening complications in burn patients undergoing hyperbaric therapy include aspirations, inadequate resuscitation with hypovolemia and metabolic acidosis, inadequate ventilation with respiratory acidosis, electrolyte abnormalities with associated cardiac dysrhythmias, hypothermia, and barotraumas.⁵⁵ Inhalation injury complicated by cardiac arrest is uniformly fatal regardless of aggressive therapy, including hyperbaric oxygen.⁵² Hydrogen cyanide toxicity, which may occur in structural fires, disrupts cellular oxidation and causes lactic acidosis, which resolves with ventilation in most patients without the need for sodium thiosulfate treatment.⁵⁶ Data are beginning to emerge on the safety of hydroxocobalamin administration for cyanide toxicity, but benefits of this early intervention have not been adequately verified to warrant this as a standard of care.⁵⁷

Upper Airway Thermal Injury

Upper airway burns occur due to hot air or chemical toxins and can be diagnosed by direct visualization of the posterior pharynx at the time of intubation. The heat absorptive capacity of the oropharynx is sufficiently efficient that thermal burns to the lower airway are rare; steam can cause a lower airway thermal burn.

Direct thermal damage tends to occur in the upper airway because the oropharynx has a substantial capacity to absorb heat. Upper airway thermal injury constitutes an important indication for intubation, because it is mandatory to control the airway before airway edema develops during resuscitation.

The diagnosis of upper airway thermal injury is achieved with direct laryngoscopic visualization of the posterior oropharyngeal cavity. The decision to intubate should be based on visual evidence of posterior pharyngeal swelling, mucosal sloughing, or carbonaceous sputum coming from below the level of the vocal cords.

Treatment for upper airway injuries includes hospital admission for observation and provision of humidified oxygen, pulmonary toilet, bronchodilators as needed, and endotracheal intubation as indicated. Upper airway thermal burns usually manifest within 48 hours of injury and airway swelling usually is maximal 12 to 24 hours after the injury. A patient with an upper airway burn may require airway protection for 72 hours. In a patient with a small burn ($<15\%$ TBSA), a short course of systemic or inhaled steroids may facilitate earlier resolution of airway edema, but steroids are contraindicated in patients with large burns due to the risk of infection and failure to heal. The patient can be extubated based on pulmonary weaning parameters and the presence of an air leak around the endotracheal tube. Once it is safe to extubate, removing the endotracheal tube should be expedited because of the potential nosocomial complication of ventilator-associated pneumonia.

Lower Airway Burn Injury

Burn injury to the tracheobronchial tree and the lung parenchyma results from combustion products in smoke (Table 11.6) and, under unique conditions, inhaled steam.

Numerous irritants in smoke or the vaporized chemical reagents in steam can cause direct mucosal injury, leading to mucosal slough and bronchial edema, bronchoconstriction,

TABLE 11.6

PRODUCTS OF COMBUSTION THAT CAN BE PREDICTED TO CAUSE SIGNIFICANT PULMONARY PARENCHYMAL INJURY

■ SOURCE	■ PRODUCT OF COMBUSTION
Organic matter	Carbon monoxide Carbon dioxide
Petroleum products (gasoline, kerosene, propane, plastics)	Carbon monoxide, nitrogen oxide, benzene
Wood, paper, anhydrous ammonia	Nitrogen oxides (NO, NO ₂)

Wool, silk, polyurethane (nylon)	Hydrogen cyanide
Wood, cotton, paper	Aldehydes
Polyurethane (nylon)	Ammonia

and bronchial obstruction. Tracheobronchial mucosal damage and loss of ciliary clearance of the debris induce parenchymal inflammation, which leads to exudate formation and microvascular permeability, and ultimately⁵⁰ may progress to pulmonary edema, pneumonia, or acute respiratory distress syndrome (ARDS). Significant inhalation of aerosolized toxins can reduce myocardial contractility and cause resuscitation failure. Whereas diagnosis of lower airway inhalation injury can be confirmed by bronchoscopy, a scoring system to correlate degree of pulmonary injury and outcome has yet to be developed. Xenon¹³³ ventilation-perfusion scan⁵⁸ has also been used for diagnosis but often underdiagnoses the extent of injury and does not change the clinical outcome.⁵⁹ Therefore, these technologies may help with documentation of a clinical diagnosis but they are not crucial to subsequent management. Given the high rate (up to 50%) of pneumonia⁴⁶ in patients with lower airway inhalation injuries, successful treatment requires aggressive pulmonary toilet and frequent chest physiotherapy.

Acute Respiratory Distress Syndrome

ARDS is an independent risk factor for death in burn patients.^{60,61} Understanding of ARDS pathophysiology and management has improved since its initial description in the late 1960s,⁶² but 40% to 70% of patients with ARDS still die.

ARDS is defined by the clinical findings of pulmonary edema, hypoxemia, diffuse pulmonary infiltrates, and reduced lung compliance; radiographic findings may be nonspecific. Histologically, ARDS has diffuse alveolar epithelial damage, microvascular permeability, and subsequent inflammatory cell infiltration into the lung parenchyma; interstitial and alveolar edema; hyaline membrane formation; and, ultimately, fibrosis.

The development of ARDS is often presaged by high fluid resuscitation requirements reflecting increased microvascular permeability and leading to increased pulmonary edema. ARDS commonly develops within 7 days after injury. Burn patients with inhalation injury have as much as a 73% incidence of respiratory failure (defined by hypoxemia, pulmonary infections, or prolonged ventilator support) and a 20% incidence of ARDS compared to burn patients without inhalation injury, who have a 5% incidence of respiratory failure and a 2% incidence of ARDS.⁶³ Advanced age may also be a risk factor for development of ARDS.⁶⁴ Acute lung injury rarely devel-

ops in patients with inhalation injury but without cutaneous burns.^{51,65}

FLUID RESUSCITATION

Most patients undergo resuscitation without difficulty. However, approximately 15% of patients with thermal injuries fail resuscitation⁶⁶ in spite of significant attention to improving fluid management of the burn patient.⁶⁷ Vascular access should be obtained early during the evaluation before swelling obscures venous markings. Two large-bore peripheral intravenous (IV) lines should provide adequate prehospital venous access; since the early burn is not contaminated with bacteria, these IV lines can be placed through eschar, but care should be taken to secure them well. For children, intraosseous cannulae can provide temporary lifesaving resuscitation, but intravenous access should be obtained as soon as possible.

Multiorgan failure due to inadequate resuscitation and decreased tissue perfusion was a common cause of death in burn patients before formulas were developed to estimate fluid needs.⁶⁸ Several proposed fluid resuscitation formulas estimate fluid requirements in the patient with large burns, suggesting that no one formula satisfactorily estimates fluid requirements for all patients. It is essential to remember that each of these formulas estimates fluid needs. However, fluid volumes should be constantly adjusted based on patient physiologic responses during resuscitation (urine output, alert sensorium, and blood pressure). Patients may require more or less fluid depending on the size and depth of burn (deeper burns often are associated with a greater inflammatory response and higher fluid needs), presence of inhalation injury, associated injuries, or comorbidities. Other clinical indicators of higher volume requirements include mechanical ventilation and high base deficit.⁶⁹

One of the commonly used resuscitation formulas has been the Baxter (or Parkland) formula, which calls for 3 to 4 mL of crystalloid per percentage TBSA burned over 24 hours. Half of this volume is delivered during the first 8 hours after injury; the other half is delivered over the subsequent 16 hours. If a patient receives all of the 24-hour estimated volume during the first 2 hours after injury, that fluid will likely leak into the interstitial extracellular tissues and the patient still must receive the estimated hourly crystalloid volumes to maintain intravascular volumes. The reliability of the Parkland formula directly depends on an accurate initial assessment of burn depth and size as described earlier. The trend since Baxter originally proposed this formula has been to administer more fluid than patients require. Some studies report volumes approaching 8 mL/kg per percent TBSA burn,⁷⁰ but whether this impacts long-term outcome is difficult to demonstrate.⁷¹

4 Reliable clinical resuscitation endpoints include maintaining a mean arterial blood pressure greater than 60 mm Hg and urine output of 30 mL/h for adults. Pediatric fluid requirements often exceed formula estimates⁷² likely due to less-well-developed renal concentrating abilities. Therefore, the urinary output goal for infants and very young children (<20 kg) should be 1.5 mL/kg per hour. Large-volume crystalloid boluses should be restricted to hypotensive episodes and should be accompanied by an increase in the hourly volume by 10%. Decreased urine output for 1 to 2 hours does not require a large-volume crystalloid bolus and should be managed by increasing the hourly resuscitation fluid rate by 10%. Stabilization of the flux of mediators and closure of capillary leaks occur gradually 12 to 48 hours after the burn injury. As capillary leak resolves, the amount of fluids needed to maintain these endpoints should progressively decrease and the IV rate generally can be slowly weaned by 10% per hour. Most burn patients do not require pulmonary arterial pressure monitoring

FIGURE 11.4. Myoglobinuria with dark pigment in the urine.

during resuscitation and will be overresuscitated if IV fluid administration is based on pulmonary artery wedge pressures. A pulmonary artery catheter may be useful in patients with underlying cardiac comorbidity at risk for cardiac shock and congestive heart failure.

Patients with extremely deep burns, electrical burns, or compartment syndrome may develop rhabdomyolysis with myoglobinuria (Fig. 11.4) and subsequent acute tubular necrosis. In these patients, a brisk urine output of 100 mL/h should be maintained. Alkalinization of the urine with intravenous sodium bicarbonate (0.12 to 0.5 mEq/kg per hour) theoretically increases myoglobin solubility and decreases precipitation in the renal tubules but requires careful serum pH monitoring and lacks clinical verification. Rarely, osmotic diuresis with mannitol is required to maintain urine output, but this treatment should be carefully considered since osmotic diuresis reduces urine output reliability as an endpoint for determining intravascular volume status.

Colloid administration (albumin or fresh frozen plasma) after the capillary leak has closed (12 to 72 hours postinjury) may restore intravascular volume in patients with persistent low urine output and hypotension despite adequate crystalloid administration. In such cases, 5% albumin (0.3 to 0.5 mL/kg per percent TBSA burn) can be administered over 24 hours. Plasmapheresis also reduces intravenous fluid requirements in patients who do not respond to standard crystalloid resuscitation. Indications for plasmapheresis include a sustained mean arterial pressure of less than 60 mm Hg and urine output less than 30 mL/h in a patient whose ongoing fluid needs are more than twice fluid volume estimates. Early plasmapheresis (12 to 24 hours postinjury) appears to decrease the incidence of complications from administration of excessive fluid such as extremity compartment syndromes, abdominal compartment syndrome, and pulmonary edema. The mechanism by which plasmapheresis works is unknown, but theoretically the plasma exchange removes circulating cytokines that cause vasodilatation and capillary leak and drive the systemic inflammatory response.

Once resuscitation is complete (24 to 48 hours postinjury), insensible losses and hyperthermia associated with a hyperdynamic state may require ongoing maintenance intravenous or enteral fluid administration. Reliable daily weights are often useful for determining insensible fluid losses or fluid retention.

Fluid Resuscitation Complications

Overresuscitation^{70,73} causes complications such as poor tissue perfusion, abdominal or extremity compartment syndrome, pulmonary edema, and pleural effusions. Increased abdominal pressure decreases lung compliance and impedes lung expansion, resulting in elevated airway pressures and hypoventilation.

Because of the risk for compartment syndrome in patients undergoing large-volume resuscitation, burned extremities should be elevated and hourly neurovascular examinations should be performed; tight bands of eschar are often evident before vascular inflow is compromised and indicate the need for escharotomies. Decreased chest compliance with circumferential burns can also improve with thoracic escharotomies, especially in children. An effective thoracic escharotomy must extend along each anterior axillary line and connect at the infraclavicular and subcostal lines (Fig. 11.5A). Extremity escharotomies should extend through the skin only and should not violate the fascia; the arm must be in anatomic position when medial and lateral incisions are made (Fig. 11.5B). Eschar on the dorsal hand must often be released to restore signals in the palmar arch (Fig. 11.5C); there is no benefit to digital escharotomies and risk of injury to the digital arteries and nerves is significant.

Abdominal compartment syndrome also classically decreases venous return, causes oliguria, and increases intra-abdominal pressures exceeding 25 mm Hg.⁷⁴ Bedside decompressive laparotomy through burn wounds, if necessary (Fig. 11.6), can alleviate abdominal compartment syndrome⁷⁵ in patients with hemodynamic instability, hypoventilation, and elevated abdominal pressures. In addition, pulmonary edema increases risk of ARDS.

Recently, orbital compartment syndrome has been reported as one more complication related to high-volume resuscitation. Patients with massive fluid resuscitation with or without facial burns develop intraocular pressures as high as 90 mm Hg, which returns to a normal range with lateral canthotomy.⁷⁶

Composition of the resuscitation fluid is important to prevent electrolyte imbalance and acidosis. Typically, lactated Ringer solution is the primary resuscitative fluid because of the risk for metabolic hyperchloremic acidosis and hypernatremia in patients who receive large volumes of 0.9% normal saline solution. The resuscitative fluid solution should not contain glucose because hyperglycemia and osmotic diuresis may confound resuscitation. Pediatric patients who weigh less than 20 kg do not have large glycogen stores in their liver and should receive 0.45% saline with 5% dextrose at a maintenance rate (3 to 4 mL/kg per hour).

WOUND MANAGEMENT

Topical Antimicrobials

- 5 It is worth emphasizing that prophylactic systemic antibiotics do not have a role in the management of the patient with acute burn injuries.⁷⁷ Because eschar is devitalized and avascular, systemic antibiotics cannot reach the eschar surface where the bacterial colonization occurs. Topical antimicrobial agents delay wound colonization and infection, but they themselves have not changed mortality in the way that early excision and grafting did. All agents commonly used in the United States have benefits and side effects (Table 11.7).

Silver sulfadiazine is the most commonly used antimicrobial agent for burns because it has a broad spectrum of antimicrobial activity, is soothing, and has no significant metabolic or electrolyte implications. Because silver sulfadiazine does not penetrate eschar, it is ineffective against already established burn wound infections. Silver sulfadiazine has been associated with

FIGURE 11.5. Escharotomies can be useful for improving chest-wall compliance and relieving extremity compartment syndromes but are very unaesthetic unless a fascial excision will be necessary. **A:** For torso escharotomies, incisions across the infraclavicular and subcostal chest that connect the anterior axillary incisions facilitate ventilation, especially in children. **B:** Extremity escharotomies are performed with the limb in its anatomic position along the medial and lateral axes. **C:** Hand escharotomies should be placed in the spaces between the metacarpals.

early postburn neutropenia, but this is more likely related margination of neutrophils due to the overall inflammatory response to injury rather than to the topical agent. The neutropenia is typically self-limited and rarely requires a change in antimicrobial therapy. Patients with sulfa allergies typically do not have adverse

FIGURE 11.6. Decompressive laparotomy can be safely performed through a burn but significantly increases morbidity and should be avoided by closely monitoring fluid resuscitation.

reactions to silver sulfadiazine; a test patch in a small area of the burn will cause pain or a rash in the unusual case of an allergy.

Mafenide acetate is unique because it penetrates eschar, making it effective in both treating and preventing burn wound infections. This attribute has led to its frequent use on the ears to protect against suppurative chondritis; however, silver sulfadiazine appears to be equally effective.⁷⁸ Mafenide provides excellent coverage against gram-negative organisms. Mafenide is available as either a cream or a solution, which is a useful topical agent for skin grafts when the wound bed is considered likely to benefit from postoperative antimicrobial treatment. The major disadvantage is that mafenide inhibits carbonic anhydrase and causes metabolic acidosis that may complicate ventilator management. Topical mafenide can be painful, especially on application to partial-thickness burns.

Silver nitrate provides broad-spectrum antimicrobial coverage, including good activity against staphylococci and gram-negative organisms, but it does not penetrate eschar well. Dressings must be irrigated with the aqueous 0.5% solution every 4 hours to keep the dressing moist and prevent precipitation of the silver nitrate onto the wound surface. Since concentrated silver nitrate causes a chemical burn, the bacteriostatic solution used for burn wounds is very hypotonic (it is reconstituted in water rather than saline to avoid silver chloride precipitation) and causes osmotic dilution in the tissues, leading to hyponatremia and hypochloremia. These can

TABLE 11.7**ADVANTAGES AND DISADVANTAGES OF ANTIMICROBIAL TOPICAL AGENTS**

■ ANTIMICROBIAL AGENT	■ COVERAGE	■ ADVANTAGES	■ DISADVANTAGES
Silver sulfadiazine	■ Broad spectrum, especially <i>Pseudomonas</i>	■ Soothing	■ Poor eschar penetration ■ May impede epithelial cell migration
Mafenide acetate	■ Broad spectrum, including <i>clostridium</i>	■ Good eschar penetration ■ Excellent for both treatment and prophylaxis	■ Carbonic anhydrase inhibition with 2° metabolic acidosis ■ Painful
Silver nitrate	■ Broad spectrum	■ Excellent prophylaxis	■ Poor eschar penetration ■ Hyponatremia ■ Methemoglobinemia
Bacitracin	■ Gram-positive bacteria	■ Good for shallow facial burns	■ Expensive ■ Often delivered in combination with neomycin and polymyxin B, which are nephrotoxic
Mupirocin	■ Methicillin-resistant <i>Staphylococcus</i>	■ Excellent for methicillin-resistant <i>Staphylococcus</i>	■ Very expensive
Silver-impregnated gauze	■ Broad coverage	■ Good for shallow burns, grafts, and donor sites	■ Hides wound ■ Can cause discomfort when dried ■ Nonadhesive and slips from wound

become severe enough to warrant treatment with oral salt tablets. Use of silver nitrate solution can also rarely lead to methemoglobinemia, which can be successfully treated with intravenous methylene blue⁷⁹; treatment should also include discontinuation of the silver nitrate. A secondary disadvantage of silver nitrate solution is that it stains everything black.

Bacitracin, neomycin, and polymyxin B can be used for coverage of superficial wounds in conjunction with petrolatum gauze to promote epithelialization and minimize bacterial colonization. These ointments are commonly used for superficial face burns. All three should be limited to relatively small burns because of potential nephrotoxicity. Mupirocin has the advantage of being effective against methicillin-resistant *Staphylococcus aureus* (MRSA) and its use should be restricted for this indication.

Several recently introduced dressings are impregnated with silver, which has unique antimicrobial properties and works by disrupting bacterial cellular respiration. These dressings can be used for superficial partial-thickness burns, donor sites, and meshed skin grafts. An advantage of these dressings is a reduced need for dressing changes since they can stay in place until a shallow burn or donor site heals. The reduced frequency of dressing changes simplifies burn care but can hinder evaluation of evolving partial-thickness burns, so its use should be limited to wounds that are likely to heal or do not need frequent evaluations. Since the silver-impregnated dressings are nonadherent, an adhesive tape such as Hypafix (Smith & Nephew) must be placed along the edge of the dressing to secure the dressing to the wound bed. After 10 to 14 days, the tape can be removed and the dressings can be washed and towel-dried daily until they peel off the epithelialized wound.

Burn Excision and Grafting

approach,^{80–83} mortality in burn patients has dramatically dropped and functional outcomes have improved over the past 30 years. Other advantages include shortened length of hospital stay,⁸⁴ lower costs,⁸⁵ and fewer reconstructive surgeries.⁸⁶ The timing for initial excision of deep burn wounds should occur as soon after the resuscitative phase of recovery as feasible. Excising large burns during the first 24 hours complicates fluid resuscitation with the risk of hypothermia and bleeding and is not recommended. By 3 to 4 days after injury, burn excision and wound coverage should be a safe option depending on the patient's hemodynamic and pulmonary status, comorbidities, and associated injuries. A patient with large, deep, partial-thickness or full-thickness burns should undergo the initial excision within 7 days of injury. Staged excisions can be performed every 2 to 3 days until the entire burn wound is excised. However, many burns are not homogeneous with both shallow and deep areas. Such indeterminate-depth burns can be safely treated with topical antimicrobial ointment for 7 to 10 days until the deeper portion that requires grafting becomes evident; this situation is common in patients with scald or grease burns. By 72 hours after injury, an experienced burn care provider can often differentiate burns that will heal with topical antimicrobial treatment within 3 weeks from deeper injuries that will require excision.

Surgical excision of the burn wound involves one of two technical approaches: fascial excision or tangential excision. Fascial excision involves excising the burned tissue and the underlying subcutaneous tissue down to the muscle fascia using electrocautery, which limits surgical bleeding (Fig. 11.7A). Advantages of a fascial excision include an easily defined, well-vascularized plane that can readily accept a graft. A major disadvantage to this approach is the inevitable removal of healthy, viable subcutaneous tissue, which leads to unaesthetic contour deformities; without the cushioning of the subcutaneous tissue, the grafts on the fascia are often fragile for years after the injury.

Tangential excision involves sequential excision of eschar until the wound bed displays diffuse punctate bleeding⁸⁷ indicative of viable tissue that can support a skin graft (Fig. 11.7B).

6 The beneficial impact of early excision and grafting on outcomes following thermal injuries has been remarkable. Because of this change in therapy from a nonoperative to an operative

FIGURE 11.7. A: Fascial excision limits bleeding but results in suboptimal aesthetic outcomes and should be avoided if possible. If necessary because of burn depth, care can be taken to tack down the edges to minimize the ledge that interferes with function. B: Tangential excision requires serial tissue removal until the wound bed has diffuse punctate bleeding; ideally this allows a thin pearly white dermal layer to remain in the wound bed.

Tangential excision can be performed with a handheld knife (Weck or Watson) adjusting the guard to control depth of excision. A disadvantage of tangential excision includes diffuse bleeding from the wound bed. As surgeons have become more comfortable with early excision and grafting, they have developed strategies to minimize surgical blood loss. Topical epinephrine solution (1:10,000), electrocautery, and compression were recognized early on to minimize blood loss. With experience, other methods evolved including using pneumatic tourniquets for extremity burns and using subeschar injection of dilute epinephrine solution to vasoconstrict the capillaries before excision. Both of these techniques require substantial experience to assess tissue viability since there will be no diffuse bleeding in the wound bed. A commercially available fibrinogen and thrombin spray system (Artiss Fibrin Sealant; Baxter, Deerfield, IL) improves hemostasis and promotes graft adherence to the wound bed with fewer and smaller underlying postoperative fluid collections.^{88,89}

Wound Closure Alternatives

Once the eschar is excised to viable tissue, the wound should be closed as soon as possible, ideally with immediate autografting. Whereas the best cutaneous replacement would be full-thickness skin grafts, this is not possible for most patients, especially those with large burns and limited donor sites. Traditionally, wounds that could not be autografted immediately were covered with a biologic dressing while donor sites healed. Human allograft is one temporary biologic dressing that is meshed 1:1 and applied to excised wound beds to allow wound drainage. Allograft vascularizes and engrafts and provides physiologic wound closure for 2 to 4 weeks, at which point it typically is rejected and must be replaced with either new allograft or preferably autograft from reharvested donor sites. Porcine xenograft can also be used as a cheaper alternative, but it will not vascularize and will not engraft. When widely meshed skin grafts are necessary, overlaid sheets of allograft can be used on top of the autografts to protect the wound bed as the meshed interstices epithelialize.⁹⁰ This minimizes wound bed desiccation and reduces pain. The disadvantage of this technique is the long time until definitive wound closure, the need to recrop donor sites, and the potential for significant hypertrophic scar formation in the interstices of the widely meshed grafts (Fig. 11.8A) and in the reharvested donor sites.

Alternative approaches using skin substitutes have improved patient long-term functional and aesthetic outcomes. Two types of skin substitutes exist: epidermal and der-

mal. Both technologies have advantages and disadvantages (Table 11.8).

Epidermal skin substitutes consisting of cultured autologous keratinocytes with or without a subjacent layer of autologous fibroblasts suggested great promise for scarless wound closure in the late 1980s.⁹¹ Whereas future advances in burn wound management will depend on improvements in cultured epithelial cell technology,^{92,93} current available products have not significantly evolved burn wound management. Dermal substitutes have been more successful in early clinical use.^{94,95} Integra dermal template (Integra Lifesciences, Plainsboro, NJ) is one commercially available product, designed to be combined with ultra-thin autograft⁹⁶ or cultured epithelium. Its advantage is that it is a bilaminate product composed of a temporary outer silastic layer and an inner matrix layer of type 1 collagen and chondroitin sulfate.^{97,98} The silastic layer provides early wound closure following eschar excision and the inner layer serves as a template that autologous fibroblasts, endothelial cells, and other mesenchymal cells populate. Once the product is vascularized (2 to 3 weeks), an ultra-thin autograft can be placed on the neodermis.⁹⁶ Histologic evaluation suggests that the Integra neodermis architecture is more comparable to uninjured dermis than regular scar (Fig. 11.9A). Integra use has been reported to have improved long-term aesthetic and functional results (Fig. 11.9B) but requires

FIGURE 11.8. Traditional widely meshed skin grafts leave hypertrophic interstices long after the wounds are mature.

TABLE 11.8

ADVANTAGES AND DISADVANTAGES OF SKIN SUBSTITUTES

	■ DERMAL SUBSTITUTES	■ EPIDERMAL SUBSTITUTE
Pros	<ul style="list-style-type: none">■ Useful with limited donor sites■ Replaces mesenchyme■ Thin donor sites■ Decreases scar formation	<ul style="list-style-type: none">■ Useful with limited donor sites■ Replaces epidermis■ Fewer donor sites
Cons	<ul style="list-style-type: none">■ Expensive■ Prone to infection■ Requires completely viable wound bed■ Requires fastidious postoperative wound care	<ul style="list-style-type: none">■ Expensive■ Prone to infection■ Prone to sheering■ Prolonged immobilization with delayed rehabilitation■ Prolonged length of stay

meticulous surgical excision and postoperative care to minimize infection.⁹⁹ A topical antimicrobial agent is usually necessary postoperatively; if neodermal quantitative cultures demonstrate more than 10⁶ colony-forming units, directed systemic antibiotics might also be indicated. A significant advantage is the rapid healing and minimal scarring in ultra-thin donor sites (Fig. 11.9C).

Another promising dermal substitute is AlloDerm (LifeCell, Woodlands, TX), a cryopreserved human dermal allograft.¹⁰⁰ The advantage of this product is the native mesenchymal structure without the allogenic cellular components that cause allograft rejection. This dermal substitute requires immediate autografting since there is no outer barrier.

METABOLIC AND NUTRITIONAL SUPPORT

Patients with major thermal injury develop a hypermetabolic state characterized by increased basal metabolic rate, increased oxygen consumption, negative nitrogen balance, and weight loss. Subsequently, these patients have increased caloric requirements¹⁰¹ to prevent delayed wound healing, decreased immune competence, and cellular dysfunction.

Protein catabolism in a 60-kg patient with a large burn may result in loss of 150 to 200 g of nitrogen per day. Nitrogen excreted in the urine can be measured, but large amounts of nitrogen lost from wounds are insensible. Therefore, measured

FIGURE 11.9. A: Histology of Integra neodermis appears more like uninjured dermis than regular scar. B: Integra covered with ultra-thin skin grafts (arrows) is softer and more elastic than the traditional wide meshed grafts. C: Donor sites for the ultra-thin grafts heal quickly without the long-term scars typical of standard-depth donor sites.

TABLE 11.9**NUTRITIONAL ASSESSMENT OF BURN PATIENTS**

	■ WOUND SIZE (% TBSA)	■ NITROGEN LOSS FROM WOUNDS (g/kg/d)	■ PROTEIN LOSS FROM WOUNDS IN A 60-kg ADULT (g/d)	■ NUTRITIONAL NEEDS
Small burn	<10	0.02	~8	Oral intake only
Moderate burn	11–30	0.05	~19	Supplemental enteral feeding if oral intake is insufficient
Large burn	>31	0.12	~45	Enteral feeding to meet nutritional goals with oral intake as tolerated

24-hour total urea nitrogen levels underestimate nitrogen losses in burn patients (Table 11.9).¹⁰²

The catabolic state continues until the wounds are closed. Once a patient becomes anabolic, preburn muscle takes three times as long to regain as it did to lose.^{103,104} Several equations can be used to estimate calorie needs. The Harris-Benedict equation estimates basal energy expenditure according to gender, age, height, and weight; the basal energy expenditure is multiplied by an activity factor that reflects the severity of injury or the degree of illness. For burns, this multiplier is 2, the maximal factor for this formula. The Harris-Benedict equation overestimates caloric needs for patients with a moderate burn size. The Curreri formula¹⁰⁵ based on patient weight and burn size overestimates caloric needs for patients with large burns and is best used for patients with small or moderate-sized burns (<40% TBSA).^{106,107}

Infection, ARDS, or creation of donor sites increases catabolism and alters caloric needs.¹⁰⁸ Healing and skin grafting close wounds and decrease the catabolic state. Hence, repeated evaluation of the metabolic state of a burn patient is necessary to account for changes in wound size and clinical condition. As discussed earlier, 24-hour total urea nitrogen levels in the urine must be augmented to estimate nitrogen losses from the wound. Serum albumin levels are not sensitive markers of adequate nutrition; they are typically low in patients with burns larger than 20% TBSA.¹⁰⁹ Transthyretin or prealbumin levels correlate more closely with catabolic status and a trend over several weeks may correlate with patient caloric needs.¹¹⁰ C-reactive protein levels provide an indication of the patient's general inflammatory state and may correlate with catabolic status.¹¹¹ Indirect calorimetry may be useful for measuring caloric needs in intubated burn¹¹² patients by quantifying oxygen consumption and carbon dioxide expiration and calculating nutritional requirements based on the formula: $\text{kcal/day} = (3.9 \times \text{VO}_2 + 1.1 \times \text{VCO}_2) \times 1.44$. Pulmonary artery catheters can also indirectly provide this information by using the Fick equation: $\text{kcal/day} = \text{cardiac output} \times (\text{arterial } \text{pO}_2 - \text{venous } \text{pO}_2) \times 10 \times 6.96$. Recent reports suggest that in children, respiratory quotients may not accurately estimate feeding needs.¹¹³

Enteral Nutrition

Prolonged ileus and stress ulcers in burn patients have been largely eliminated by early feeding.¹¹⁴ Multiple studies have shown that patients with major thermal injury can receive adequate calories soon after injury. At the University of Washington Burn Center, tube feeding is started a median of 5 hours after admission (unpublished quality improvement data).

Benefits of gastric feeding versus duodenal feeding continue to be debated. Although feeding distal to the pylorus theoretic-

cally should cause less aspiration risk, enteral formulas can be found in pulmonary secretions of 7% of patients receiving gastric feeds compared with 13% of patients receiving transpyloric feeding.¹¹⁵ Hence, for burn patients with high caloric needs, the delay in feeding for confirmation of tube placement may not be worth the effort.

Continuation of tube feeds during surgery in intubated burn patients who require multiple operations maximizes caloric intake and decreases wound infection.¹¹⁶ However, intraoperative repositioning may necessitate stopping feeds preoperatively, especially if the patient will be prone. Critically ill burn patients who have undergone decompressive laparotomy for abdominal compartment syndrome also tolerate continuous tube feedings.¹¹⁷

Glucose Management

Hyperglycemia negatively impacts wound healing and increases morbidity and mortality in critically ill patients, even those without underlying diabetes mellitus.¹¹⁸ Increased risk of infection, reduced skin graft take, and higher mortality¹¹⁹ underscore the importance of maintaining blood sugars between 80 to 120 mg/dL.¹¹⁸ In spite of the initial excitement about the beneficial effect of tight glucose control on outcomes of critically injured patients, increasing data suggest that very tight control does not improve outcomes in trauma patients¹²⁰ and should be studied prospectively in burn patients.¹²¹

Albumin

Hypoalbuminemia typically persists in burn patients until the wounds are healed. Patients with large burns typically have serum albumin levels of 1.7 g/dL and rarely exceed 2.5 g/dL.¹⁰⁹ Administration of exogenous albumin to attain serum levels above 1.5 g/dL does not appear to impact length of stay, complication rate, or mortality.¹²²

Nutritional Supplementation

Studies to determine benefits of specialized nutritional supplements such as arginine, glutamine, and omega-3 fatty acids in burn patients are contradictory.^{123–125} However, there are reports that anabolism can be promoted in burn patients with metabolically active agents such as insulin, recombinant human growth factor, the anabolic steroid oxandrolone, and propranolol.¹²⁶ Oxandrolone in particular has been reported to improve weight gain and functional recovery in burn survivors.¹²⁷ Propranolol has now been fairly well characterized as having a beneficial effect in

pediatric patients¹²⁸ and should be investigated in a multicenter trial for adults. Early administration of the antioxidants α -tocopherol and ascorbic acid reduces the incidence of organ failure and shortens ICU length of stay in critically ill trauma patients.⁷⁷ Whereas a multicenter study will be necessary to demonstrate similar results in burn patients, the potential benefit and the low cost make antioxidant supplementation an attractive low-risk intervention for burn patients at risk for multiorgan dysfunction.

INFECTION

We have determined that as many as 80% of patients with large burns developed an infection from one or more sources during the hospital stay (unpublished data). Judicious antibiotic use must be employed to limit development of opportunistic infections in patients and to establish responsible epidemiologic infection control in the burn unit. Therefore, targeted systemic antibiotics should be used for diagnosed infections based on clinical judgment and supportive laboratory and radiologic findings. Prophylaxis against gram-positive organisms leads to development of gram-negative bacterial infections or fungal and mold infections and are therefore contraindicated in patients with burns.¹²⁹ Fungal wound infection has been reported to be independently associated with mortality in burn patients regardless of burn size, age, or presence of inhalation injury.¹³⁰ Tetanus prophylaxis continues to be recommended since the disease is so devastating and vaccination has few theoretical risks. However, current medical literature has few reports of tetanus developing in patients who have been immunized during childhood.¹³¹

DEEP VEIN THROMBOSIS

The incidence of deep vein thrombosis (DVT) has been reported to be as high as 25% in hospitalized burn patients.¹³² It has also been reported to be responsible for only 0.14% of deaths in burn patients; hence, a standard of care for DVT prophylaxis in burn patients has never been defined.¹³³ One study has suggested that age and burn size have a synergistic effect on DVT/pulmonary embolism risk, with the sum of age and TBSA burn having the strongest independent effect ($p < 0.001$).¹³⁴ At the University of Washington Regional Burn Center, patients with burns larger than 20% TBSA developed clinically evident thromboembolic disease in 9% of those who received prophylaxis with unfractionated heparin and in 18% of those who received low-molecular-weight heparin (unpublished quality improvement data). On the basis of these data, patients with burns larger than 20% TBSA receive prophylaxis with subcutaneous unfractionated heparin, 5,000 U three times per day. A dropping platelet count suggests heparin-induced thrombocytopenia, which causes generalized microvascular thrombosis and can be associated with thromboembolic disease.

ANEMIA

Acute blood loss soon after injury is uncommon in a patient with an isolated burn injury; therefore, a dropping hematocrit during resuscitation may be a sign that a patient has associated injuries or a bleeding diathesis. Procedures such as central venous line placement or escharotomies should not be associated with significant blood loss.

Patient age, overall condition, and comorbidity should contribute to the determination for the need for a transfusion. The risks of viral transmission, transfusion reaction, and cost must also be considered. For a healthy patient who does not need

surgery, a hematocrit as low as 20% may be well tolerated. However, inhalation injury, infection, or multiorgan failure may require a higher hematocrit to maximize oxygen-carrying capacity. Patients with large burns and anticipated blood loss should receive iron supplements. Erythropoietin is an expensive recombinant supplement that has not been shown to prevent anemia or decrease transfusion requirements in acutely burned patients.¹³⁵

PAIN MANAGEMENT

Pain management for patients with burn injuries works best with simple pharmaceutical approaches. Use of several narcotics with varying half-lives will confuse health care providers, the patient, and the family. However, burn patients experience three different classes of pain, background, breakthrough, and procedural pain, which require different approaches.

Burn patients experience background pain 24 hours per day until their wounds are healed; long-acting pain relievers are well suited for this type of discomfort. A hospitalized patient with large burns can be easily treated with methadone or controlled-release morphine sulfate. An outpatient with a small burn often does well with a nonsteroidal anti-inflammatory drug; ideally these should be stopped at least 7 days before surgery.

Breakthrough pain occurs when exercise or other activities of daily living exacerbate background burn wound discomfort. Short-acting narcotics or acetaminophen can alleviate occasional breakthrough pain. Persistent breakthrough pain suggests that the long-acting medication dosage should be increased.

Procedural pain occurs during wound care and dressing changes and usually requires treatment with a short-acting narcotic. For inpatients with larger burns, oral narcotics or transmucosal fentanyl citrate^{136,137} works well for wound care; IV morphine or fentanyl can be used for uncontrolled pain. For outpatients, oxycodone (5 to 15 mg) usually suffices for daily wound care. Anxiety about wound care or therapy is often misconstrued as pain, especially in children, and is likely undertreated.¹³⁸ Therefore, patients with large burns requiring daily wound care should be evaluated for potential benefit from a short-acting anxiolytic agent for procedures. Complications of excessive narcotic use, such as prolonged sedation, delirium, and, more urgently, loss of airway control, must be avoided in young children and elderly patients, who may have decreased narcotic tolerance.¹³⁹

Nonpharmacologic approaches can augment pain management in burn patients. Hypnosis can be administered either by trained health care providers or by patients themselves to reduce narcotic use in burn patients.¹⁴⁰ Virtual reality has also shown promise as a distraction modality to enhance patient comfort during wound care and intense therapy.¹⁴¹

Discomfort in the healed wound due to paresthesias and itching may persist for months after injury but generally does not respond to narcotics; exercise and deep massage are effective modalities that patients should be encouraged to use. Diphenhydramine, cyproheptadine, or cetirizine may relieve itching. Use of doxepin ointment may also abrogate itching in healed wounds. Keeping the wound moist with a topical salve or lotion may be as effective as other pharmacologic approaches.

SPECIALIZED BURN AREAS

Burns of the Face, Ocular Adnexa, and Ears

The structures in the midface can be difficult to excise and reconstruct. Therefore, the face is commonly treated nonoperatively with topical antimicrobial agents for 10 days.^{142,143}

Areas that remain unhealed at that time should be excised and grafted with thick sheet autograft. The nasal tip and alar rims are especially difficult to reconstruct and excision should be sparing. Periocular burns can lead to acute and late sequelae. Early after injury, edema can cause conjunctival desiccation with eventual keratitis and corneal ulceration. Lubrication with ophthalmologic antibiotics is mandatory but tarsorrhaphy may be necessary. If the lid burns are deep, earlier excision and full-thickness skin grafting may be indicated. Ear burns can lead to suppurative chondritis if infection develops. Many texts suggest that all ear burns must be treated with mafenide cream,¹⁴⁴ but studies have verified that silver sulfadiazine has comparable results.⁷⁸ More importantly, pressure on the burned auricle from objects such as pillows and tight dressings or ties should be avoided by using a foam egg crate for a pillow and very loose dressings.

Burns of the Hands and Feet

Optimal functional outcome of hand burns is facilitated by an organized, multidisciplinary approach to the injuries with emphasis on the therapist. The initial evaluation of the burned hand must include evaluation of capillary refill, temperature, and Doppler signals in the palmar arch. It is not enough simply to demonstrate that there is blood flow in the radial or ulnar arteries. If the arm or upper arm is circumferentially burned, escharotomies of the proximal upper extremity and dorsal hand may be indicated (Fig. 11.5B, C). Digital escharotomies are never indicated because the potential injury to the digital vessels and nerves outweighs the benefits. For high-voltage electrical injury or deep fourth- or fifth-degree thermal burns, fasciotomy may be required for forearm compartment syndrome or progressive neurovascular impairment. In equivocal cases, it is most prudent to proceed to decompression promptly rather than wait until ischemia has advanced.

Extremity elevation benefits hand burns by limiting edema and subsequently allowing range of motion and limiting risk of infection. Active range of motion should be the goal for all

hand burns; this will decrease edema and maintain manual function. If the patient is unable to cooperate, passive range of motion should be performed at least twice per day. Splinting the hand in a functional position, with the metacarpophalangeal joints at 70 to 90 degrees, the interphalangeal joints in extension, the thumb in neutral position with the first web space open, and the wrist in 20 to 30 degrees of extension, may be indicated for a critically injured patient. Deep partial-thickness and full-thickness burns should be excised and sheet grafted as soon as practical (Fig. 11.10). Hands are immobilized in a functional position for 5 days after surgery to prevent shearing of the graft before range-of-motion exercises are resumed. Deeper hand burns that involve the extensor mechanisms, joint capsules, or bone are difficult clinical problems. They also often require temporary or long-term axial Kirschner wire fixation of open and unstable interphalangeal or metacarpophalangeal joints. These burns may require groin or abdominal flap coverage¹⁴⁵ to achieve a tissue bed that can be grafted. With these approaches patients with deep hand burns should be able to function independently.

Palm burns are especially common in the toddler age group as they begin to explore and touch hot surfaces such as ovens or gas-fireplace glass. Since palmar skin is thick, many burns do not require resurfacing. Therefore, a nonoperative approach facilitates preservation of the specialized attachment of the palmar skin to the underlying fascia and regeneration of the unique Pacinian mechanoreceptors in the palmar skin. If necessary, full-thickness injuries that do not heal in 3 to 4 weeks or show signs of healing by contraction should be grafted with full-thickness or thick split-thickness sheet grafts and splinted in extension to maintain the palm in an open position. Likewise, burns of the plantar surface of the feet should be grafted with full-thickness or thick split-thickness sheet grafts if they fail to heal within 3 weeks.

Genital Burns

Genital burns should be investigated for suggestion of abuse or neglect. A burned foreskin must be reduced to a normal

FIGURE 11.10. A: A deep grease/flame burn to the hand can be grafted as soon after injury as feasible to expedite return to function. B: Sheet grafts for the hands provide the optimal functional and aesthetic outcomes.

position so edema does not cause paraphimosis. Penile and scrotal burns often heal well without excision and grafting. Urethral stenting and bladder catheter drainage are not required for genital burn management and increase the risk of urinary tract infection. Bladder catheters should be removed when close monitoring of the urine output is no longer required. Likewise, diversion of the intestinal tract is not required in the management of perineal burns.

MISCELLANEOUS BURN INJURIES

Electrical Injuries

As with many areas of burn care management, electrical burns have little level 1 evidence to support treatment algorithms.¹⁴⁶ Electrical injuries can be grouped into three categories: high voltage, involving contact with more than 1,000 volts; low voltage, caused by contact with less than 1,000 volts; and those caused by lightning. Electrical flash burns occur when a high-voltage current arcing (jumping) from a high-tension wire toward a human being generates heat and produces a flash skin burn; this does not involve electrical current and should not be confused with an electrical injury. Low-voltage injuries may cause locally destructive injuries but rarely cause systemic sequelae. High-voltage injuries can cause local destruction at the contact wounds, a deep-tissue injury secondary to the passage of current, deep wounds where the current arcs across joints, flash burns or deep flame burns if clothing ignites, axial spine fractures due to tetanic contraction of paravertebral muscles, and other blunt injuries related to a fall. Hence, patients with high-voltage electrical burns require a complete trauma evaluation including radiographic skeletal series, cardiac monitoring, bladder catheterization to evaluate the urine for presence of myoglobinuria, and serial neurovascular exams in extremities at risk for compartment syndrome; because many electrical injuries involve the hand, carpal tunnel syndrome and impaired median nerve function deserve special immediate attention. Increased compartment pressures due to edema of the injured muscle leads to additional ischemic injury and rhabdomyolysis and warrant immediate fasciotomy; likewise, progressive loss of median nerve function suggests that a carpal tunnel release may be indicated. Surveys of trauma and burn surgeons suggest that practices vary with regard to cardiac monitoring and musculoskeletal workup; given a paucity of evidence-based data on outcomes following electrical injuries, establishing standards of care for treating this injury is challenging.

A low-voltage electrical injury especially unique to children occurs when a child puts an electrical extension cord connector into his or her mouth to pull the two plugs apart. The classic finding is a full-thickness tissue injury to the lateral mouth (Fig. 11.11) with delayed bleeding from the labial branch of the facial artery when the eschar falls off. Maintaining the oral opening is essential to prevent contracture.

Late sequelae of high-voltage electrical injuries include progressive sensory and/or motor neurologic loss and early cataract formation; these can develop within weeks to months of the injury. All patients admitted for evaluation and treatment of a high-voltage electrical injury should undergo a comprehensive neurologic and ophthalmologic examination to establish baseline status.

Chemical Injuries

Regardless of whether a chemical burn is alkali or acid, the initial treatment should be copious irrigation with tap water for 30 minutes. Cement and concrete powder or powdered lye should be brushed dry from the patient since contact with water activates the aluminum hydroxide. For eye burns, topical oph-

FIGURE 11.11. Full-thickness tissue destruction due to an electrical burn to the commissure of the mouth in young children can lead to oral contractures. The importance of range-of-motion exercises must be emphasized to the parents.

thalmic anesthetics can facilitate relief of the conjunctivitis and blepharospasm that limits affective irrigation; ophthalmologic antibiotics should be used if a fluorescent examination confirms presence of a corneal abrasion.

Hydrofluoric acid is one chemical that does have a specific antidote since exposure can induce life-threatening hypocalcemia as the fluoride binds calcium in the tissue.¹⁴⁷ In addition to irrigation with water, topical calcium gluconate gel can be soothing¹⁴⁸ but is inefficient. These burns are often located on the hands of manual workers and can be treated with slow intra-arterial calcium gluconate infusion over 4 hours.¹⁴⁹ This approach requires cardiac monitoring in an ICU. If the burn involves a large area and hypocalcemia persists, emergency burn wound excision may be indicated.

Tar Injuries

Tar is often heated to more than 300°F and commonly causes a deep burn, especially if the source is the “mother pot.” Adherent tar can be initially cooled by tap water irrigation to limit the progression of the injury. It can be easily removed from the skin (Fig. 11.12) with a lipophilic solvent such as Medi-Sol (The Orange-sol Group of Companies, Gilbert, AZ). Once the wound is exposed, it can be treated like other thermal injuries with topical antimicrobial ointments until the need for surgery is determined.

NONACCIDENTAL BURN INJURIES

Neglect and abuse affect enough children that providers should consider these diagnoses in any child that has burns. If there is any question that either contributes to the injury, the child should be admitted to the hospital for further assessment.⁹ If expert opinion suggests that the injuries are suspicious, they should be filed with the appropriate local agency. Radiographic evaluation of the head, ribs, and long bones

FIGURE 11.12. A: Congealed tar should be removed with a lipophilic solvent to determine whether there is a burn underneath. B: Cleaning wounds thoroughly with Medi-Sol is safe and essential for correctly determining an accurate burn size.

should be obtained for further documentation of other types of abuse; ophthalmologic evaluation should also be performed to rule out retinal detachment, often a sign of shaken baby syndrome. Too often abuse in other vulnerable populations is overlooked; learning disabled and the elderly¹⁵⁰ are at-risk groups and suspicious injuries should be reported to adult protective services.¹⁵¹ Finally, self-mutilation should be treated cautiously. Even patients with multiple small burns such as cigarette burns should be admitted for psychological evaluation.¹⁵²

NONBURN CONDITIONS COMMONLY CARED FOR IN BURN CENTERS

Wound care and critical care services in burn centers^{153,154} lend themselves to management of other conditions with large cutaneous deficits such as purpura fulminans, toxic epidermal necrolysis, staphylococcal scalded skin syndrome, or major soft tissue avulsions.

- 9 Toxic epidermal necrolysis (TEN) (Fig. 11.13A), scalded skin syndrome (Fig. 11.13B), and graft versus host disease (Fig. 11.13C) are similar blistering disorders with vastly different etiologies. TEN, a variant of erythema multiforme major, involves epidermal slough at the dermal-epidermal junction. Common associations include sulfa drugs, anticonvulsants, and nonsteroidal anti-inflammatory agents, but non-specific viral syndromes may be the only prodromic event leading to the skin loss. This condition is characterized by sloughing of all stratified squamous epithelial cell surfaces including the oral mucosa and anus. Typically, the skin between the blisters can be sheared with minimal digital pressure in a test known as a Nikolsky sign. Treatment depends on extent of skin slough. Small, scattered areas can be treated with silver-impregnated dressing or greasy gauze. When epidermal sloughing involves more than 25% TBSA, gentle débridement of the confluent areas of sloughed skin and placement of a biologic dressing such as xenograft¹⁵⁵ is indicated to prevent skin desiccation and superinfection (Fig. 11.13D); this approach has been associated with a 19% mortality rate,¹⁵⁶ which is lower than national reports of mortality after TEN. Systemic steroid treatment is associated with poorer prognosis, as are topical treatment with silver nitrate solution and total peripheral nutrition.¹⁵⁷ Recent suggestions that the process can be effectively limited with intravenous immunoglobulin (IVIG) treatment¹⁵⁸ have not been defini-

tively demonstrated in clinical trials. Prophylactic antibiotics are associated with increased mortality. Patients with severe oropharyngeal involvement may require intubation for airway protection and early enteral tube feeding while the oral lesions heal. Daily ophthalmologic evaluation is essential to prevent synechiae forming. Likewise, daily separation of the external genitalia and vaginal lubrication are indicated to prevent painful mucosal scarring.

Differentiation between TEN and staphylococcal scalded skin syndrome can be difficult on clinical grounds, and if there is a question, a skin biopsy for histologic confirmation is warranted. Patients with scalded skin syndrome typically do not present with positive blood cultures since the staphylococcal exotoxin is responsible for the epidermal separation at the granular layer. These wounds are more superficial than TEN and usually heal quickly. Mucous membrane and conjunctiva involvement are not typical and may provide a useful differentiation between staphylococcal scalded skin syndrome and toxic epidermal necrolysis.

Empiric antistaphylococcal antibiotics should be administered, but a detailed physical examination should be performed to identify a source of infection.

Purpura fulminans is typically a complication of meningococcal or streptococcal sepsis.¹⁵⁹ Many patients with this condition have multiorgan failure due to the underlying septic shock coupled with the significant vasopressive agents required for cardiovascular support; ischemia affects end organs including patchy cutaneous necrosis (Fig. 11.14A), especially the digits (Fig. 11.14B). Treatment of the wounds is supportive until the patient is stable enough to undergo excision and grafting; excision or amputation may be indicated earlier if the necrotic wounds become superinfected. Amputations are common in survivors.

Necrotizing Soft Tissue Infection

- 10 Necrotizing fasciitis should be considered in any patient with cellulitis and a history of IV drug abuse, diabetes, obesity, vascular insufficiency, or immunosuppression. Signs and symptoms that differentiate a necrotizing infection (Fig. 11.15A) from uncomplicated cellulitis reflect the severity of illness and are summarized in Table 11.10. Delayed diagnosis and surgical treatment are associated with significantly increased mortality. If a necrotizing soft tissue infection is suspected, wider surgical débridement should be performed emergently (Fig. 11.15B). A central venous catheter should be placed for fluid

FIGURE 11.13. A: Toxic epidermal necrolysis (TEN), a severe variant of erythema multiforme major, causes distinct blisters and a characteristic Nikolsky sign (*arrow*) of normal-appearing skin sloughing between the bullae. B: Scalded skin with diffuse erythema appears more diffuse and when the skin sloughs, the underlying epidermis is often healed. C: Graft versus host disease can be confused in appearance with TEN, but history of a recent transplant (solid or hematologic) is pathognomonic. D: Removal of the sloughed skin and protection of the underlying viable wound bed by applying a biologic dressing such as xenograft improves survival in patients with TEN.

resuscitation and preoperative antibiotics penicillin (4 million units), gentamicin (7 mg/kg), and clindamycin (1,200 to 1,600 mg) should be administered. During wide débridement of necrotic tissue, an immediate Gram stain and culture swab should be obtained and reviewed. One should assume clostridia infection if there are gram-positive rods with a

paucity of white blood cells and assume β -hemolytic streptococcal infection if there are abundant gram-positive cocci. Plans should be made to reexplore the wound within 24 hours of the original operation; this may be sooner if the patient undergoes clinical deterioration or if the white blood cell count increases. Broad-spectrum antibiotics should be continued

FIGURE 11.14. Purpura fulminans resulting from meningococemia or streptococemia causes patchy cutaneous necrosis on many body surfaces (A), but especially the digits (B).

FIGURE 11.15. A: Necrotizing soft tissue infections must be differentiated from cellulitis based on systemic physiology. B: Wide surgical débridement of all involved tissues is the mainstay of treatment for this life-threatening tissue infection, even if it exposes vital structures.

until the microbiology results are final. For patients in septic shock, perioperative IVIG may be indicated to bind the toxin. Anecdotal evidence also indicates that plasmapheresis might improve outcome in septic patients.

HYPERTROPHIC SCARRING AND RECONSTRUCTIVE SURGERY

Hypertrophic scar formation is a devastating complication of burns and partial-thickness wounds (Fig. 11.16). The scars are raised, hyperemic, warm, and very pruritic, reflecting the histologic findings of increased microvessels²⁸ and nerves.^{40,41} We know from clinical experience that hypertrophic scars form in wounds that take longer to heal, suggesting that wound depth is important. We also know that they occur in anatomic locations such as the presternal chest and central face more frequently than sites such as the forehead, scalp, and palms or soles. Hypertrophic scars are more prevalent in patients with pigmented skin, especially Asians and Hispanics. The decreased incidence in elderly patients with atrophic skin and senescent cellular responses suggests that high cellular activity may contribute to scar formation. Despite the misery associated with

hypertrophic scar formation, our understanding of the pathophysiology is very limited; this basic lack of knowledge is aggravated by the absence of an animal model of scar hypertrophy. However, recent studies suggest that the female red Duroc pig generates a fibroproliferative scar¹⁶⁰ that parallels many clinical, histologic, and biochemical findings in human hypertrophic scar tissues.

The ability to regulate development of hypertrophic scars is limited, as is treatment for the symptoms. Custom-fit compression garments are worn within 2 weeks of wound healing and often continue until the wounds mature at 1 or 2 years after injury. Topical silicone anecdotally improves hypertrophic scar size and symptoms, but the mechanism is not clear and skin irritation and rashes can accompany use. Intradermal steroid injection has also been described but is very painful and unreliable in the management of hypertrophic scarring; furthermore, the wound size that can be treated is limited by the risk of systemic steroid effects. Patients with persistent symptomatic hypertrophic scarring that limit function or activities of daily living often require excision and primary wound closure or wound closure with sheet autografts or tissue flaps. Patients who have survived large burns may require several sequential reconstructive procedures during the first few years after injury to attain optimal cosmetic and functional results.

TABLE 11.10

SIGNS AND SYMPTOMS OF NECROTIZING SOFT TISSUE INFECTION

White blood cell count >20,000
Thin, gray drainage
Marked induration
Edema of entire limb
Hyponatremia (Na <135 mEq/L)
Skin blistering/sloughing
Skin necrosis
Crepitus/soft tissue gas on radiography
Pain out of proportion to skin findings
Sepsis (tachycardia, hypotension, high fluid requirements)

If patient meets any of these criteria, consider early surgical consultation.

FIGURE 11.16. Hypertrophic scars in healed deep partial-thickness burns cause considerable patient discomfort and misery due to the itching, warmth, raised appearance, and often functional limitations.

REHABILITATION AND RECONSTRUCTION

As survival following major burns has improved, more emphasis has been placed on functional recovery, societal reintegration, and return to school or work. In the early 1990s, the National Institute of Disability and Rehabilitation Research (NIDRR; <http://www.ed.gov/offices/osers/nidrr>), whose mission is to generate, disseminate, and promote new knowledge to improve independent living options for disabled persons, recognized that burn survivors would likely benefit from organized rehabilitation model systems that had been established for survivors of traumatic brain injuries. Since then, the NIDRR has continuously funded projects to advance knowledge in burn rehabilitation by providing multicenter grants to four centers of excellence.

Physical function requires continual participation of burn occupational and physical therapists from the time of the acute injury until long after discharge from the hospital. Initially, therapists are involved with twice-daily passive or active range-of-motion exercises of all joints and positioning and splinting of the hands, extremities, or neck. In patients with small burns or in those with almost healed large injuries, therapy involves strengthening, ambulation, active and passive range of motion, performance of activities of daily living, and, in older adolescents and adults, development of work-related skills and, if necessary, development of adaptive skills with modified utensils or prosthetic devices. Therapists often provide the essential human bridge between inpatient and outpatient care.

Posttraumatic stress, anxiety, or depression frequently manifests after severe burns. Whereas burns that involve the hands or face can be anticipated to induce these symptoms, they cannot be otherwise predicted based on burn size or location. Preinjury psychiatric conditions, family dysfunction, or substance abuse further complicate psychosocial recovery. The major impact that psychological recovery has on the burn patient's ability to recover functionally underscores the need for coordinated participation of burn psychologists and social workers in the multidisciplinary care of burn patients. These staff members typically interact with the patient, family, and local outpatient support services throughout hospitalization and assist with coordinating discharge plans.

CHAPTER 12 ■ ANESTHESIOLOGY AND PAIN MANAGEMENT

SACHIN KHETERPAL, TIMOTHY W. RUTTER, AND KEVIN K. TREMPER

KEY POINTS

- 1 Anesthetics are generalized depressants of consciousness, pain, cardiopulmonary function, motor function, and recall.
- 2 To prevent movement and to facilitate the surgical exposure, neuromuscular blocking agents are generally used. These drugs are competitive or noncompetitive inhibitors of the neurotransmitter acetylcholine at the neuromuscular junction.
- 3 Opioids produce profound analgesia and respiratory depression. They have no amnesic properties, minimal direct myocardial depressive effects, and no muscle-relaxant properties.
- 4 Propofol is unique because it is rapidly cleared through hepatic metabolism to inactive metabolites in a way that the patient becomes alert soon after cessation of the infusion. However, as the duration and dose of the maintenance infusion is increased, the time to return of consciousness is also significantly increased.
- 5 Peripheral nerve blockade can be used in lieu of general anesthesia to provide surgical anesthesia or as a postoperative pain management technique. Use of long-acting local anesthetics or placement of an indwelling continuous catheter provides long-term (16 hours to several days) pain relief.
- 6 The concept of airway management should be focused on not just endotracheal intubation, but also mask ventilation. Until the airway can be secured via intubation, the patient must be supported through mask ventilation. The key elements of an airway examination are an assessment of obesity, mouth opening, neck flexion and extension, Mallampati oropharyngeal classification, presence of beard, and mandibular protrusion ability.
- 7 Hypertension is the most common preexisting medical disease in patients presenting for surgery and is a major risk factor for renal, cerebrovascular, peripheral vascular, and coronary artery diseases as well as for congestive heart failure.
- 8 The appropriate duration to defer elective surgery after coronary stenting remains controversial, but recent guidelines from the American College of Cardiology/American Heart Association recommend 12 months for drug-eluting stents and 6 weeks for bare-metal stents. The role for antiplatelet therapy remains a major question, but data suggest that cessation of recommended antiplatelet therapy in the perioperative period may have significant coronary thrombotic risks without major improvement in bleeding adverse events.
- 9 The three goals of the preoperative evaluation are (a) to develop an anesthetic plan that considers the patient's medical condition, the requirements of the surgical procedure, and the patient's preferences; (b) to ensure that the patient's chronic disease is under appropriate medical therapy before an elective procedure; and (c) to gain rapport with and the confidence of the patient, answer any questions, and allay fears.
- 10 Patients receiving chronic pain or opioid addiction therapy with buprenorphine (Subutex, Suboxone) can be particularly challenging to manage in the postoperative period and should be immediately referred to their primary care physician and an anesthesiologist to create a pain management plan prior to the day of surgery. Buprenorphine is mixed opioid agonist/antagonist that tightly binds at the μ receptor and has a long and varied half-life (24 to 60 hours). It can inhibit the analgesic benefits of traditional opioids in the postoperative period, resulting in uncontrolled pain, decreased patient satisfaction, and the potential for adverse events due to the need for very high doses of opioids.
- 11 As positive-pressure ventilation impedes venous return within a closed thorax, decreases in systolic pressure associated with a respiratory pattern can be detected. In patients with sinus rhythm with stable cardiac contractility, the degree of systolic pressure variation (SPV) reflects the intravascular volume status of the patient. The normal range of SPV is 5 to 10 mm Hg.
- 12 Postoperative acute pain management may require a multimodal approach that incorporates opioids, peripheral nerve blockade, and nonopioid analgesics. Chronic pain patients can be particularly difficult to manage and may require preoperative optimization by an anesthesiologist.

The “state of general anesthesia” is a combination of hypnosis, amnesia, analgesia, and muscle relaxation. This state can be achieved by administration of single or multiple anesthetic agents via inhalational or intravenous routes. Historically, anesthesia was achieved by inhaling volatile anesthetic vapors that produced each of these conditions in proportion to the concentration achieved in the central nervous system. Anesthesia can also be achieved by using a balance of multiple pharmacologic agents, each targeted to produce a specific effect. These are the hypnotic/sedatives, analgesics, and neuromuscular blocking agents. As the concentration of hypnotic/sedative and analgesic agents increases, cardiovascular and respiratory functions may be progressively blunted. For this

reason, modern anesthetics usually require titration of these agents to optimize conditions for the surgery while maintaining cardiovascular stability.

The goals of modern anesthesia are (a) to create a reversible anesthetic state quickly and safely by choosing the appropriate techniques and agents considering the patient's medical condition, (b) to maintain this state throughout the surgical procedure while compensating for the effects of varying degrees of painful stimuli and fluid loss, and (c) to reverse the muscle relaxation and hypnosis, bringing the patient back to a homeostatic state while maintaining sufficient analgesia to minimize postoperative pain. This process is accomplished with a high degree of safety 30 to 40 million times a year in the United States, despite

the serious potential complications of technical or judgment errors. The high degree of success of both surgical and anesthetic outcomes is due to the efforts of thousands of surgeons and anesthesiologists who have advanced the art and science of their field.¹ Although modern surgical techniques, regional or neuraxial blockade procedures, and systemic analgesics have made it possible to ameliorate perioperative pain, significant challenges in postoperative pain management remain. Pain not only is unpleasant, but it also has significant adverse physiologic effects and physicians should encourage patients to alert health care personnel when pain is felt.

ANESTHETIC AGENTS AND THEIR PHYSIOLOGIC EFFECTS

Inhalation Agents

1 Anesthetics are generalized depressants of consciousness, pain, cardiopulmonary function, motor function, and recall. The potent inhalation agents (e.g., isoflurane, sevoflurane, desflurane) produce these effects in a dose-dependent fashion. The measurement used to compare the potency of inhalation agents is the minimum alveolar concentration (MAC), an empirically derived number defined as the expired percent concentration required to prevent movement on painful stimulation (incision) in half of experimental subjects. There is significant patient-to-patient variability independent of underlying comorbidities. Compounding this variability are the effects of age, weight, preexisting heart disease, liver disease, and medications other than the inhalational anesthetic. Table 12.1 lists the commonly used inhalation agents and their MACs and side effects. In general, all agents depress blood pressure by

myocardial depression and vasodilation, resulting in system hypotension. There is a generalized depression of cerebral function and cerebral metabolic rate of oxygen consumption, although cerebral blood flow may increase because of cerebrovascular dilatation and a loss of coupling. Renal blood flow and glomerular filtration rate are reduced by 20% to 50%. The body's normally tight regulation of core body temperature is lost, resulting in a redistribution of heat from the core to the periphery. The combination of these effects, the cold environment of the operating room, and open body cavities make the patient extremely vulnerable to hypothermia (core body temperature <36°C).

Intravenous Sedatives/Hypnotics

Several commonly used intravenous sedative/hypnotic medications can also be used in lieu of an inhalational anesthetic to achieve the hypnotic component of the state of anesthesia. A constant intravenous infusion of these medications is used to achieve and maintain a blood concentration that results in the loss of consciousness and prevents recall. Unlike the inhalational agents, there currently is no ability to measure the patient's expired or blood concentration of these intravenous agents. As a result, the infusion rate is titrated to effect by observing patient movement (if muscle relaxants are not used concurrently) and hemodynamic responses to procedural stimuli. Of note, the sedative/hypnotic intravenous agents do not possess clinically useful muscle relaxant or analgesic properties and must be combined with other agents to deliver a "balanced" anesthetic. The most commonly used intravenous agent for maintenance of anesthesia is propofol, a lipid-soluble substituted isopropyl phenol that produces hypnosis and sedation through interactions with γ -aminobutyric acid (GABA), the

TABLE 12.1

COMMON INHALATION AGENTS: MINIMUM ALVEOLAR CONCENTRATIONS AND EFFECTS

AGENT	MINIMUM ALVEOLAR CONCENTRATION (%)	STRENGTHS	WEAKNESSES
Nitrous oxide	105	Analgesia Rapid uptake and elimination Little cardiac or respiratory depression	Sympathetic stimulation Expansion of closed air spaces Interference with vitamin B ₁₂ metabolism Limitation of FiO ₂
Isoflurane	1.15	Good muscle relaxation Stable cardiac rate and rhythm Usability in neurosurgery	Pungent odor
Desflurane	6	Rapid induction and emergence	Pungent odor Causes coughing High vapor pressure (Boiling point 23.5°C) Requires special pressurized vaporizer High cost
Sevoflurane	1.71	Rapid induction and emergence Less pungent Good for mask induction	Moderate cost Metabolized in liver and produces increased plasma fluoride Canister fires with Baralyme

FiO₂, fraction of inspired oxygen.

primary inhibitory neurotransmitter of the central nervous system. When administered as a continuous infusion, propofol can achieve minimal levels of sedation, deep sedation, or general anesthesia. Additional details regarding the use and side effects of propofol are discussed later. Other classic agents such as benzodiazepines can also be used as maintenance infusions, but do not enable the rapid return to consciousness that propofol offers. A novel, highly specific α_2 -receptor agonist, dexmedetomidine, has recently demonstrated an exciting role as an intravenous sedative/hypnotic that also has analgesic effects. In the perioperative setting, it is currently limited to use as an adjunct to propofol and inhalational anesthetics.

Muscle Relaxants

- 2 To prevent movement and to facilitate the surgical exposure, neuromuscular blocking agents are generally used. These drugs are competitive or noncompetitive inhibitors of the neurotransmitter acetylcholine at the neuromuscular junction. The only noncompetitive inhibitor used clinically is succinylcholine. This drug rapidly binds to the nicotinic receptors and produces depolarization at the neuromuscular junction, clinically obvious as fine muscle fasciculations occurring about 60 seconds after injection. Succinylcholine cannot be reversed, but has a short duration of action (<10 minutes) because it is quickly hydrolyzed in the plasma by cholinesterase. Because of rapid onset, succinylcholine is frequently used to facilitate endotracheal intubation when it must be accomplished quickly.

All other clinically useful muscle relaxants are termed *competitive inhibitors* and do not cause depolarization when they attach at the neuromuscular junction. Because these agents compete with acetylcholine, the block produced is in direct proportion to the concentration of the agent relative to the concentration of acetylcholine. If the concentration ratio is low enough,

competitive relaxants can be reversed if the concentration of acetylcholine is artificially elevated. Acetylcholine concentration can be increased by giving a drug that blocks its metabolism, an anticholinesterase (e.g., neostigmine). The neuromuscular blocking agent is still present, but motor function returns if the acetylcholine concentration is high enough to overwhelm the blocking agent. There is a ceiling to which anticholinesterase drugs can safely elevate circulating acetylcholine; therefore, high levels of nondepolarizing relaxants cannot be reversed. Reversing neuromuscular relaxants is not analogous to using naloxone to reverse the effects of opioids. The reversal agent neostigmine does not compete or combine with the relaxant.

Unfortunately, there are systemic consequences to increasing the plasma concentration of acetylcholine. Acetylcholine is the predominant neurotransmitter in the preganglionic sympathetic and parasympathetic nervous systems and in the postganglionic parasympathetic nervous system. For this reason, an anticholinergic drug (atropine or glycopyrrolate) must be given with the anticholinesterase to prevent the undesirable effects of a generalized acetylcholine overdose. The common neuromuscular blocking drugs and their doses, durations, and side effects are listed in Table 12.2; common regimens of reversal agents are shown in Table 12.3.

A novel class of compounds, known as *selective relaxant binding agents*, is currently under phase III clinical trials. They are able to rapidly reverse the effects of profound levels of muscle relaxation created by steroidal muscle relaxant agents such as rocuronium, vecuronium, or pancuronium. Rather than attempting to increase the concentration of acetylcholine, these agents actually bind free muscle relaxant molecules within its cyclodextrin ring structure. This decreases the concentration of free muscle relaxant and allows acetylcholine to function normally at the neuromuscular junction. The cyclodextrin-muscle relaxant combination is then eliminated via the kidney. The first cyclodextrin used for this purpose, known as sugammadex, is being reviewed by the U.S. Food

TABLE 12.2

COMMON NEUROMUSCULAR BLOCKING DRUGS AND REVERSAL AGENTS

MUSCLE RELAXANT	INTUBATING DOSE (mg/kg)	INFUSION DOSE (mg/kg/min)	STRENGTHS	WEAKNESSES
DEPOLARIZING				
Succinylcholine	1.0	100 ^a	Fastest onset (30 to 60 s) Short duration ^b (5 min)	Associated with malignant hyperthermia, dysrhythmias, bradycardia, and hyperkalemia, especially in patients with burns or neurologic injury
NONDEPOLARIZING				
Long acting (>1 h)				
Pancuronium	0.1	0.3	No histamine release	Tachycardia Slow onset Long duration
Intermediate acting (≈1 h)				
Cisatracurium	0.2	0.1	Spontaneous degradation, not affected by renal or liver disease	Moderate cost
Vecuronium	0.1	1	No cardiovascular effects	
Rocuronium	0.8	10	Fast onset, no cardiovascular effects	

^aThis should not be used for longer than 1 h.

^bDuration is dramatically increased in patients with abnormal plasma pseudocholinesterase.

TABLE 12.3**DRUGS FOR ANTAGONIZING NONDEPOLARIZING NEUROMUSCULAR BLOCKADE^a**

■ DOSE	■ TIME TO PEAK EFFECT (min)	■ DOSE	■ USE WITH	■ COMMENTS
ANTICHOLINESTERASES				
Edrophonium	1–2	0.5–1.0 mg/kg	—	Very fast onset, not commonly used
Neostigmine	3–5	0.04–0.07 mg/kg	—	Most commonly used
Pyridostigmine	10–12	0.2–0.3 mg/kg	—	Not used clinically for neuromuscular reversal
ANTICHOLINERGICS				
Glycopyrrolate	—	0.008 mg/kg (0.5–0.6 mg/70 kg)	Neostigmine Pyridostigmine	Not commonly used in adults
Atropine	—	0.007–0.02 mg/kg (0.05–1.5 mg/70 kg)	Edrophonium	CNS effects because it crosses the blood–brain barrier

CNS, central nervous system.

^aFor reliable results in reversing the effects of nondepolarizing muscle relaxants, administration of anticholinesterases is delayed until spontaneous recovery permits three of four responses to a train-of-four stimulus. For patients with more profound blockade, larger amounts of anticholinesterases may be required, but doses of neostigmine higher than 0.14 mg/kg are unlikely to produce additional improvement.

Adapted from Watling SM, Dasta JF. Prolonged paralysis in intensive care unit patients after the use of neuromuscular blocking agents: a review of the literature. *Crit Care Med* 1994;22:884.

and Drug Administration (FDA) and European Union for clinical use.² These drugs could revolutionize the practice of anesthesiology by enabling the rapid (<3 minutes) reversal of profound muscle relaxation as surgical conditions warrant.

Nondepolarizing relaxants are occasionally used in critically ill patients who are difficult to manage. For example, neuromuscular blockade can facilitate ventilation of patients with adult respiratory distress syndrome who require complex modes of ventilation. It is imperative that these drugs be given in conjunction with analgesics and amnesic agents. Neuro-muscular blocking agents have no analgesic or amnesic properties and only prevent motion of voluntary muscles. Patients can be totally aware and in pain but unable to communicate. When prolonged muscle relaxation is required, it is best to administer the relaxant by continuous infusion and then monitor the effect with a nerve stimulator. For these settings, relaxants should be administered only to achieve the degree of relaxation necessary and in a dose that allows reversal at any time. Table 12.2 includes the recommended ranges of infusion rates. In recent years, there have been reports of patients who have prolonged residual motor weakness after the muscle relaxant is cleared.³ These problems have been primarily noted with the drug pancuronium, especially when the patients are also being treated with steroids.

All muscles in the body are not equally sensitive to muscle relaxants. The diaphragm is most resistant to neuromuscular blockade, whereas the neck and pharyngeal muscles that support the airway are most sensitive. It is possible for an intubated patient to spontaneously ventilate and even to produce a large negative inspiratory effort and yet develop complete airway obstruction when extubated because of the effects of residual muscle relaxant on the upper airway muscles. The definitive clinical test for complete reversal of neuromuscular blockade is the patient's ability to sustain a head lift from the bed for 5 seconds.

Opioids (Narcotics) and Other Intravenous Analgesics

Narcotics and synthetic analogues belong to the class of drugs called *opioids*. The most commonly used drugs in this family

are morphine, fentanyl, and codeine. Since the mid-1980s, a series of synthetic opioids have been developed with fentanyl as the prototype. More recently developed synthetics (sufentanil, alfentanil, and remifentanyl) are more potent and of varying duration (Table 12.4). Opioids produce profound analgesia and respiratory depression. They have no amnesic properties, minimal direct myocardial depressive effects, and no muscle-relaxant properties. Opioids can produce significant hemodynamic effects indirectly by releasing histamine or blunting the patient's sympathetic vascular tone because of analgesic properties. The latter effect depends on the degree of sympathetic tone that is present at baseline. Acutely injured patients may be hypovolemic and in pain, with high sympathetic tone and peripheral vascular resistance. Patients in this condition can experience dramatic drops in systemic blood pressure with minimal doses of opioids. For this reason, it is important to titrate narcotics in small incremental doses. Because of the lack of direct myocardial depression and the absence of histamine release with the synthetic opioids, they are frequently used as the primary anesthetic in combination with an amnesic agent and a muscle relaxant in patients with significant myocardial dysfunction.

When opioids are titrated intravenously, patients first become apneic because of the respiratory depressive effect (shifting the CO₂ response curve), but they still breathe on command. As the dose increases, patients become apneic and unresponsive. An unusual side effect of high-dose intravenous (IV) opioids is chest-wall muscle rigidity, which can make it extremely difficult to ventilate a patient without the assistance of a muscle relaxant.

Opioids are primarily analgesic and not amnesic. Patients can be totally aware and have substantial recall of conversations despite appearing completely anesthetized. All opioids can be reversed with naloxone. The duration of action of naloxone can be shorter than that of the opioid, and patients must be observed carefully after they have been treated with naloxone. Naloxone reversal of opioids can be dangerous because the agent acutely reverses not only the analgesic effects of the opioid but also the analgesic effects of native endorphins. Naloxone treatment has been associated with acute pulmonary edema and myocardial ischemia and should not be used electively to reverse the effects of a narcotic. It is

^cProduces pain on injection that can be reduced by treatment with 20 mg of lidocaine IV.

appropriately used in an emergency situation when the airway is poorly controlled and the patient is not ventilating because of an opioid overdose.

Propofol

4 Propofol is a lipid-soluble substituted isopropyl phenol that produces a rapid induction of anesthesia in 30 seconds followed by awakening in 4 to 8 minutes after a single bolus. Intravenous propofol can effectively produce total anesthesia (for less stimulating procedures), including amnesia, some analgesia, and some degree of muscle relaxation. Propofol is unique because it is rapidly cleared through hepatic metabolism to inactive metabolites in a way that the patient becomes alert soon after cessation of the infusion. However, as the duration and dose of the maintenance infusion is increased, the time to return of consciousness is also significantly increased. This context-sensitive half-life of propofol must be incorporated into expectations of a “quick wake-up.” Propofol has direct antiemetic properties and is a valid alternative to inhalational anesthetics in patients who have demonstrated a history of prolonged, refractory postoperative nausea and vomiting. It has an important role in intensive care units when used as a continuous infusion sedative at dosages of 25 to 50 $\mu\text{g/kg/min}$. However, prolonged infusions have been associated with a lethal metabolic derangement known as propofol infusion syndrome, characterized by a profound metabolic acidosis and cardiovascular compromise.⁴ Propofol can produce significant hypotension when IV induction doses are administered. It also produces significant pain on injection in peripheral veins. Pain can be diminished or eliminated by pretreatment with IV lidocaine via the vein to be used for propofol administration. Propofol is insoluble in aqueous solution and therefore comes dissolved in a lipid emulsion that has the associated risk of bacterial contamination. Once a vial of propofol is opened, it is not recommended that it be used after 6 hours.

Ketamine

Ketamine is a phencyclidine derivative that produces anesthesia characterized by dissociation between the thalamus and

limbic systems. Induction of anesthesia is achieved within 60 seconds after IV injection of 1 to 2 mg/kg or within 2 to 4 minutes of intramuscular (IM) injection of 5 to 10 mg/kg. Patients appear to be in a cataleptic state in which their eyes remain open with a slow nystagmic gaze. The drug produces intense amnesia and analgesia but has been associated with unpleasant visual and auditory hallucinations that can progress to delirium. The incidence of these problems can be significantly reduced if benzodiazepines are also administered with the drug. At low doses (0.1 to 0.2 mg/kg IV or 2 mg/kg IM), patients continue to spontaneously ventilate but cannot be expected to protect the airway should vomiting occur. At higher doses, ketamine acts as a respiratory depressant and produces complete apnea. Ketamine also has direct and indirect sympathetic nervous system stimulatory effects, which can be useful in hypovolemic patients. These effects are diminished or absent in patients who are catecholamine depleted. The sympathetic stimulatory effect increases myocardial oxygen consumption and intracranial pressure, and ketamine is relatively contraindicated in patients with ischemic heart disease or space-occupying intracerebral lesions. Ketamine is frequently used as an IV analgesic during debridement procedures, at doses listed in Table 12.4. Intramural ketamine (1.0 to 2.0 mg/kg) is also very useful for sedating patients who are difficult to manage (e.g., combative adult or mentally retarded patient) so IV access can be obtained.

Amnesics and Anxiolytics

Benzodiazepines are the primary class of agents used as amnesics and anxiolytics. The prototype drug, diazepam, has been more recently replaced by its water-soluble analogue of shorter duration, midazolam. Lorazepam also belongs in this family of agents, but because it has a very long duration of action, it is not routinely used intraoperatively. Lorazepam has intensive care unit applications (Table 12.5). Benzodiazepines produce anxiolysis and some degree of amnesia but have no analgesic properties. Intraoperatively, midazolam is always used in conjunction with an opioid or inhalation agent. Midazolam can be used in combination with the short-acting opioid fentanyl to produce conscious sedation for minor procedures. Benzodiazepines can produce apnea and have synergistic adverse effects with narcotics. Very small doses of midazolam

TABLE 12.5**ANXIOLYTICS AND AMNESICS (BENZODIAZEPINES)**

■ NAME	■ DOSE (mg/kg)	■ DURATION (h)	■ STRENGTHS	■ WEAKNESSES
Midazolam (Versed)	0.05 (infusion dose 0.25 mg/kg/min)	0.5	Water soluble Short duration Good for sedation for short procedures	Acute respiratory depression
Diazepam (Valium)	0.1	1	Intermediate duration	Irritation on IV injection Phlebitis Acute respiratory depression after IV overdose
Lorazepam (Ativan)	0.02–0.08	6–8	Long duration	—
BENZODIAZEPINE REVERSAL				
Flumazenil (Romazicon)	4–20 (0.2 mg repeated every 2 to 10 min until reversal is achieved) Maximum dose 1 mg	45–90 min	—	May produce seizures, panic, arrhythmias
IV, intravenous.				

and fentanyl can quickly produce an unconscious apneic patient. As with all anesthetics, benzodiazepines used as IV agents for sedation should be given in small incremental doses to achieve the desired effect. A reversal agent is also available for benzodiazepines (flumazenil). The recommended dosages of these drugs and the reversal agents appear in Table 12.5.

Local Anesthetics

Local anesthetics constitute a class of drugs that temporarily block nerve conduction by binding to neuronal sodium channels. As the concentration of the local anesthetic increases around the nerve, autonomic transmission will be blocked first, followed by sensory transmission, and then motor nerve transmission. These drugs can be injected locally into tissue to produce a field block, around peripheral nerves to produce a specific dermatomal block, around nerve plexuses to produce a major conductive block, or into the subarachnoid or epidural space to produce extensive neuroaxial blockade. All the methods have been used to assist in the provision of an alternative form of balanced anesthesia by supplementing analgesia and muscle relaxation.

Adverse consequences associated with the use of local anesthetics fall into three categories: acute central nervous system toxicity due to excessive plasma concentration, hemodynamic and respiratory consequences due to excessive conduction block of the sympathetic or motor nerves, and allergic reactions. Whenever a local anesthetic is injected, there can be inadvertent intravascular injection or an overdose of the drug because of rapid uptake from the tissues. All can produce seizures. Complications can be minimized by withdrawing before injection to avoid an intravascular injection and limiting dosages to the safe range (Table 12.6).

When local anesthetics are administered for a spinal or epidural block, they produce a progressive blockade of the sympathetic nervous system, which produces systemic vasodilation. Sympathetic nerves travel along the thoracolumbar region with the first four thoracic branches, including the cardiac sympathetic accelerators. A sympathetic blockade of this entire region produces profound systemic vasodilatation and

bradycardia. This condition is referred to as *total sympathectomy*, and the hypotension that ensues is usually below the minimal cerebral perfusion pressure required to maintain consciousness. Affected patients are bradycardic, hypotensive, unconscious, and usually apneic. This disastrous situation is easily remedied if treated quickly with a vasopressor (phenyl ephrine or ephedrine) and atropine. If not treated promptly, the situation proceeds to cardiac arrest. In this emergency situation, the treatment of high doses of epinephrine is 10 to 40 μ /kg, or 1 to 4 mg for an adult. The doses of epinephrine are higher than in a usual cardiac arrest because of the total sympathectomy.⁵ Because the level of sympathetic block is two to six dermatomal levels higher than the sensory block, it is often difficult to obtain a high spinal sensory level without approaching a total sympathectomy.

Local anesthetics are chemically divided into two groups, esters and amides. The esters (2-chloroprocaine and tetracaine) produce metabolites that are related to *p*-aminobenzoic acid and have been associated with allergic reactions. Amides (lidocaine and bupivacaine) are rarely associated with allergic reactions. If an allergic reaction does occur, it is most likely due to the preservative (methyl paraben) used in multidose vials of lidocaine.

NEURAXIAL AND PERIPHERAL NERVE BLOCKADE

Although general anesthesia is employed for millions of surgical procedures each year in the United States, many operations can be performed safely using neuraxial or peripheral nerve blockade. The two primary neuraxial techniques, a “single-shot” spinal and continuous epidural catheter, can be used for lower extremity and lower abdominal procedures. In both techniques, a small dose of local anesthetic is administered near spinal nerve roots in order to temporarily ablate sensory input from the peripheral somatic and visceral structures. In the case of a spinal anesthetic—also known as a subarachnoid block—the intrathecal sac surrounding the cauda equina at vertebral interspace L2-3 or below is located using a sterile, small-caliber

TABLE 12.6**LOCAL ANESTHETICS**

	■ MAXIMUM SINGLE DOSE (mg)	■ DURATION (h)	■ COMMENTS
AMIDES			
Lidocaine	500	1 ^a	Fast onset
Ropivacaine	200	4–12 ^a	Less cardiac toxicity than bupivacaine
Bupivacaine	200	4–12 ^a	Exaggerated cardiotoxicity with IV injection Slow onset Long duration
ESTERS^b

Tetracaine	80	0.5–1	Slow onset

IV, intravenous.
^aAddition of 100 µg of epinephrine (0.1 mL of 1:1,000) lowers the toxicity and increases the duration of the local anesthetic.
^bMetabolism to paraaminobenzoic acid may cause allergic reactions.

needle (25 gauge typically). Once cerebrospinal fluid is observed in the hub of a needle, 1 to 2 mL of local anesthetic (typically bupivacaine or lidocaine) is injected into the intrathecal space. The needle is then completely withdrawn. This local anesthetic serves to directly inactivate efferent and afferent transmission at the nerve roots it comes in contact with. Because local anesthetics are not specific to specific nerve fiber types, blockade of sensory, motor, and sympathetic nerves occurs. The spread of local anesthetic within the subarachnoid space is primarily determined by three factors: (a) the vertebral interspace accessed, (b) the density of the local anesthetic in relation to the density of cerebrospinal fluid (a concept known as *baricity*), and (c) the position of the patient during injection and immediately thereafter. In order to eliminate the risk of needle puncture of the spinal cord, subarachnoid blocks are only performed below L2-3 in adults and L3-4 in children. The local anesthetic solution may be combined with vasoconstrictors such as epinephrine or opioids such as fentanyl or morphine in order to increase the density or duration of the sensory blockade. Surgical anesthesia ranging from 1 to 2 hours can be achieved using a subarachnoid block. Because of concerns regarding permanent nerve damage, intrathecal catheters are typically not used.^{6,7} As a result, most subarachnoid blocks are “single-shot” techniques that cannot be redosed.

In the case of epidural techniques, the nerve roots are blocked outside the thecal sac in potential space between the ligamentum flavum and dura mater. This space is accessed sterilely using a 19-gauge introducer needle and a loss of resistance technique. Once the space is identified, a 21-gauge catheter is inserted into the space via the introducer needle and the needle is removed. After testing to reduce the likelihood of inadvertent intravascular or intrathecal placement of the catheter, the epidural catheter can be taped in place. Because the epidural catheter can be left in place for several days, redosing is possible. Dilute local anesthetics combined with vasoconstrictors or opioids are the mainstay of epidural therapy. Epidural neuraxial techniques can be used for surgical anesthesia, as an adjunct to general anesthesia, or for postoperative pain relief. Epidural catheters can be placed in the

thoracic or lumbar regions because the intrathecal sac is not being accessed; associated dermatomal spread and analgesia is observed. Epidural techniques often fail to result in a dense sacral nerve root blockade, so this may be a poor choice for surgical anesthesia at or below the knee.

Peripheral nerve blockade (PNB) has been used for surgical anesthesia of the extremities since the days of intravenous regional anesthesia described by Bier in 1908. Peripheral nerve blockade differs from neuraxial techniques in that it targets peripheral nerves after they have formed from the combinations of nerve roots. Upper extremity, lower extremity, and visceral peripheral nerves are targets of these peripheral nerve blocks. Historically, anatomic landmark-based identification of peripheral nerves was complemented by use of electrical stimulator needles with the hope of eliciting specific motor responses confirming correct needle placement. However, current anesthesia techniques now employ real-time ultrasound guidance of a PNB needle under direct visualization. Vascular structures and nerves are visualized in relation to a PNB needle in order to decrease the likelihood of intravascular or intraneural injection and increase the likelihood of an efficacious block. Peripheral nerve blockade can be used in lieu of general anesthesia to provide surgical anesthesia or as a postoperative pain management technique. Use of long-acting local anesthetics or placement of an indwelling continuous catheter provides long-term (16 hours to several days) pain relief.

SEDATION ANALGESIA FOR MINOR SURGICAL PROCEDURES

There are a variety of minor surgical procedures that can be accomplished safely and comfortably with anesthesia provided by infiltration of local anesthetics (most commonly 1% lidocaine) and mild sedation/anxiolysis provided by IV agents. All IV benzodiazepines, narcotics, and other IV anesthetics produce apnea if given in a high enough dose. Because there is a substantial patient-to-patient variability in response to a given dose,

FIGURE 12.1. Classification of the patient's upper airway based on the size of the tongue and the pharyngeal structures visible on mouth opening. Class I, soft palate and anterior/posterior tonsillar pillars, and uvula visible; Class II, tonsillar pillars and part of uvula hidden by base of tongue; Class III, soft and hard palate visible; Class IV, soft palate not visible, only hard palate visible. (Reproduced with permission from Stoelting RK, Miller RD. *Basics of Anesthesia*, 5th ed. New York: Churchill Livingstone; 2007:146.)

it is important that IV anxiolytics be given in small incremental doses slowly to achieve a safe sedated state. Another important factor to remember is that the anesthesia is provided by infiltration of the local anesthetic and not by the IV sedative. IV agents including narcotics cannot overcome the pain associated with a surgical incision. If large doses of narcotics are given for this purpose, once the surgical stimulus ends, the patient may quickly become apneic. The duration of the respiratory depression for even short-acting narcotics is much longer than the painful stimulus of the incision. Because of the potentially serious consequences of an apneic episode, the Joint Commission has required that all patients receiving sedation for minor surgical or medical procedures undergo the following⁸:

1. A preprocedure evaluation including an airway examination (Fig. 12.1)
2. Appropriate monitoring: pulse oximetry as a minimum
3. Documentation of the patient's vital signs and arterial saturation as well as the dose and timing of sedatives provided during the procedure

TABLE 12.7

SEDATION SCALE

■ SEDATION SCALE	■ DESCRIPTION
1	Awake and alert
2	Awake and sedated
3	Asleep but arousable to touch or verbal stimuli
4	Asleep but arousable to painful stimulus
5	Asleep and not arousable to painful stimulus

4. Documentation of a recovery period and a return to a safe recovered state

The preprocedure evaluation should include current medications, coexisting disease, and a brief physical examination including an evaluation of the airway. The most common drug used to provide sedation is midazolam. This is a fast-onset, relatively short-acting benzodiazepine that can be easily titrated to produce a sedated yet cooperative arousable state. It is usually given to adults in incremental doses of 1 mg (0.01 mg/kg in children). Narcotics such as fentanyl even in small doses act synergistically with benzodiazepines to cause a more sedated state with a much higher incidence of apnea. To assess the effect of the drug, a validated sedation scale can be of value. The scale used at the University of Michigan is presented in Table 12.7.⁹

AIRWAY EVALUATION FOR THE NONANESTHESIOLOGIST

An essential skill for all clinicians is the assessment of a patient airway. It is important to determine how difficult it may be to obtain control of the airway if a patient should require airway or ventilatory support. The concept of airway management should be focused on not just endotracheal intubation, but also mask ventilation. Until the airway can be secured via intubation, the patient must be supported through mask ventilation.¹⁰ The key elements of an airway examination are an assessment of obesity, mouth opening, neck flexion and extension, Mallampati oropharyngeal classification, presence of beard, and mandibular protrusion ability (Table 12.8).¹¹

TABLE 12.8

STANDARD AIRWAY EXAMINATION FOR NONANESTHESIOLOGISTS

■ EXAM ELEMENT	■ CONCERNING FINDINGS
Body mass index (kg/m ²)	Body mass index ≥ 31
Mouth opening	Interincisor or intergingival distance > 3 cm
Mallampati classification	Class III or IV (see Fig. 12.1)
Mandibular protrusion	Inability to protrude lower incisors to meet or extend past upper incisors
Neck anatomy	Radiation changes, or thick obese neck
Cervical spine mobility	Limited extension or possibly unstable cervical spine
Beard	Presence of full beard

Despite decades of research, there is no perfect combination of clinical tests to predict difficult intubation. However, the presence of abnormalities in three or more of the aforementioned elements increases the likelihood of a difficult mask ventilation and/or difficult intubation by more than eight times.¹¹ In patients with multiple (three or more) airway abnormalities, the presence of a beard is an easily corrected characteristic: the patient should be asked to shave the beard in order to improve the ability to manage the airway. Assessment of oropharyngeal classification is performed by having patients open their mouth and maximally protrude the tongue without phonation. This Mallampati oropharyngeal assessment can be classified depending on whether the uvula can be completely seen (class 1), only partly seen (class 2), or not seen, with only the hard and soft palate visible (class 3), or only the hard palate visible (class 4; see Fig. 12.1).¹²

RISKS ASSOCIATED WITH ANESTHESIA

7 Because the anesthetic agents effectively obtund or completely block nearly all physiologic protective mechanisms, there is an associated risk even without a surgical procedure. Fortunately, with the advent of newer agents and monitoring techniques, it is estimated that the mortality rate due to anesthesia alone has decreased from about 1 in 10,000 patients in the 1950s to as low as 1 in 200,000 or less for healthy patients today.¹³ Although a 1 in 200,000 risk of death or serious neurologic impairment may appear small, when dire consequences occur in a young patient undergoing a purely elective procedure, the consequences are devastating for everyone involved. When patients are placed in a condition in which they cannot breathe, there is always the possibility of a technical or judgmental error resulting in hypoxia and brain damage or death. It has been estimated that between 50% and 75% of anesthetic-related deaths are due to human error and are preventable. Because the consequences of an anesthetic mishap are usually severe, the emotional and financial costs are high.

The most common problems associated with adverse outcomes are related to the airway and include inadequate ventilation, unrecognized esophageal intubation, unrecognized extubation, and unrecognized disconnection from the ventilator. The incidence of these problems has been significantly reduced by including capnometry and pulse oximetry in addition to other noninvasive monitors, although a cause-and-effect relation has been difficult to prove. Efforts to improve outcome can be approached at three levels: (a) reduction of the incidence of rare but catastrophic anesthetic-related problems, (b) improvement of the care and experience of every patient undergoing anesthesia and surgery, and (c) improvement of the preparation and management of patients with preexisting medical conditions who have higher morbidity and mortality rates. The first goal has been addressed in part with improved monitoring techniques and anesthesia training. Others have been advanced by the addition of comprehensive pain management, as discussed later in this chapter. Issues of preexisting medical disease and how they affect the anesthetic plan are also briefly discussed later in this chapter.

Cardiovascular Diseases

Hypertension. Hypertension is the most common preexisting medical disease in patients presenting for surgery and is a major risk factor for renal, cerebrovascular, peripheral vascular, and coronary artery diseases, as well as congestive heart failure (CHF). It is particularly associated with lipid disorders,

diabetes, and obesity. It is these associated comorbidities that are most likely to lead to morbidity and mortality in the perioperative period, and therefore, the presence of hypertension should prompt the surgeon to review the history and physical examination for them. Hypertensive patients should be treated medically to render them normotensive before elective surgery. In general, antihypertension medications should be continued throughout the perioperative period. Recently this strategy has been questioned for patients treated with angiotensin receptor blockers (ARBs), such as valsartan, candesartan, losartan, or angiotensin-converting enzyme inhibitors (ACE-Is), such as lisinopril, captopril, or ramipril. Patients treated with these medications have experienced substantial intraoperative hypotension, which is unresponsive to standard vasopressors. This ACE-I/ARB hypotension has been treated successfully with terlipressin, vasopressin, and methylene blue.^{14–16} Some now recommend withholding ACE-Is/ARBs the morning of surgery, and data among general surgery patients indicate that withholding the medications for at least 10 hours prior to induction of anesthesia may be appropriate.^{17,18} Patients on concomitant diuretic therapy are at greatest risk for intraoperative hypotension requiring treatment.^{19,20}

The incidence of hypotension and myocardial ischemia intraoperatively is higher in untreated hypertensive patients than in adequately treated hypertensive patients if the preoperative diastolic pressure is 110 mm Hg or higher.²¹ Inadequately treated hypertensive patients undergoing carotid endarterectomies have an increased incidence of neurologic deficits, and those with a history of prior myocardial infarctions have an increased incidence of reinfarction. Patients commonly have an elevated blood pressure on admission to the hospital. Hypertensive patients can have exaggerated responses to painful stimuli and have a higher incidence of perioperative ischemia.

Coronary Artery Disease. Much of the anesthetic preoperative evaluation has historically been focused on the detection and treatment of coronary artery disease. Coronary artery disease is present in about 25% of patients who undergo surgery each year.²¹ It is the leading cause of death in the United States and continues to be a major cause of postoperative morbidity and mortality.²² The goal of the preoperative cardiac evaluation is to identify patients who are at increased risk of perioperative cardiac morbidity and ensure that their chronic conditions are optimized. Although perioperative cardiac events are the leading cause of death following anesthesia and surgery, it has been difficult to define patient characteristics that accurately predict a high risk of adverse outcome.²³ It has been even more difficult to modify that risk effectively.²⁴ Preoperative CHF is clearly a significant risk factor, as is recent myocardial infarction or unstable angina (Table 12.9). Diabetes mellitus, atherosclerotic vascular disease, and hypertension also appear to confer risk, although less than with CHF or unstable angina. Perioperative risk in patients with valvular heart disease varies with the severity of the disease as represented by CHF, pulmonary hypertension, and dysrhythmias. Dysrhythmias are also a concern in the presence of coronary artery disease. Age and stable angina remain controversial as predictors of perioperative risk, with equal numbers of supporting and refuting studies. The value of revascularization remains controversial as well. In patients without significant pulmonary disease, the ability to climb two flights of stairs without stopping or experiencing symptoms of angina or shortness of breath is considered a good practical test of cardiac reserve. Unfortunately, many patients with ischemic heart disease have concomitant pulmonary disease or other medical problems that limit their activity. A history of myocardial infarction is important information. Large retrospective studies have found that the incidence of reinfarction is related to the time elapsed since the previous myocardial infarction.^{25–27} The incidence of reinfarction appears to stabilize at about 6%

TABLE 12.9

CLINICAL PREDICTORS OF INCREASED PERIOPERATIVE CARDIOVASCULAR RISK (MYOCARDIAL INFARCTION, HEART FAILURE, DEATH)

MAJOR

Unstable coronary syndromes

Acute or recent MI^a with evidence of important ischemic risk by clinical symptoms or noninvasive study

Unstable or severe^b angina (Canadian class III or IV)^c

Decompensated heart failure

Significant arrhythmias

High-grade atrioventricular block

Symptomatic ventricular arrhythmias in the presence of underlying heart disease

Supraventricular arrhythmias with uncontrolled ventricular rate

Severe valvular disease

Intermediate

Mild angina pectoris (Canadian class I or II)

Previous MI by history or pathologic Q waves

Compensated or prior heart failure

Diabetes mellitus (particularly insulin dependent)

Renal insufficiency

MINOR

Advanced age

Abnormal ECG (left ventricular hypertrophy, left bundle-branch block, ST-T abnormalities)

Rhythm other than sinus (e.g., atrial fibrillation)

Low functional capacity (e.g., inability to climb one flight of stairs with a bag of groceries)

History of stroke

Uncontrolled systemic hypertension

ECG, electrocardiogram; MI, myocardial infarction.

^aThe American College of Cardiology National Database Library defines recent MI as >7 d but ≤1 mo (30 d); acute MI is within 7 d.

^bMay include “stable” angina in patients who are unusually sedentary.

^cCampeau L. Grading of angina pectoris. *Circulation* 1976;54:522.

after 6 months. The highest rate of reinfarction occurs in the 0- to 3-month period. Mortality from reinfarction, for patients undergoing noncardiac surgery (Table 12.10), has been reported to be between 20% and 50% and usually occurs within the first 48 hours after surgery.

Perioperative cardiac adverse event risk reduction has undergone significant changes over the past decade. Previous retrospective studies demonstrating value to coronary revascularization spurred aggressive preoperative coronary artery disease identification and management. However, recent data have questioned the value of coronary revascularization among asymptomatic patients in not only the perioperative period, but also in the general medical population.^{28,29} The most recent American College of Cardiology (ACC)/American Heart Association (AHA) guidelines reserve preoperative coronary revascularization for patients demonstrating asymptomatic left main coronary artery disease, three-vessel disease, reduced ejection fraction, unstable angina, or acute myocardial infarction.³⁰ Furthermore, large retrospective and prospective studies have demonstrated that the institution perioperative beta blockade also bears significant risks that must be weighed against possible benefits.^{31,32} As a result, the most recent

^bDo not generally require further preoperative cardiac testing.

ACC/AHA guidelines reserve the institution of beta-blocker therapy for only high-risk procedures or high-risk patients.³⁰ Patients already on beta-blocker therapy should be continued on the therapy throughout the perioperative period.³³ The widespread use of 3-hydroxy-3-methylglutaryl coenzyme A (HMG-CoA) reductase inhibitors, commonly known as statins, for cardiovascular disease and hyperlipidemia has introduced another medication into the surgical preoperative evaluation. Although prospective data establishing the value of instituting preoperative statin therapy are limited, there is general consensus that these medications should not be withdrawn during the perioperative period.³⁴

All patients in high-risk groups or with a history of ischemic heart disease must be evaluated and properly treated before elective surgery. All elective surgery should be delayed for 6 months after myocardial infarction. If this is not feasible, invasive monitoring should be considered in the perioperative period and intensive postoperative observation should continue for at least 48 hours. The intrusiveness of the surgical procedure also plays a part in the overall risk and need for preoperative workup of heart disease. The AHA has produced and updated an algorithm for the recommended preoperative workup (Algorithm 12.1).³³

Percutaneous Coronary Intervention with Stenting.

The widespread use of percutaneous intervention for coronary artery disease via angioplasty with or without stenting has introduced a new level of clinical complexity. In-stent thrombosis is a feared complication with profound morbidity and mortality. Given the known proinflammatory and prothrombotic physiologic state induced by acute illness, surgery, and anesthesia, coronary stents may be at elevated risk for thrombosis during the perioperative period. Large retrospective studies have demonstrated that the risk of perioperative in-stent thrombosis is increased if noncardiac surgery is performed soon after percutaneous coronary intervention.^{35,36} The appropriate duration to defer elective surgery after

ALGORITHM 12.1. Decision aid for preoperative cardiac evaluation prior to noncardiac surgery. This decision tree for preoperative evaluation takes into account not only the patient's physical status but also the severity of the surgical procedure. ACC, American College of Cardiology; AHA, American Heart Association; LOE, level of evidence.

coronary stenting remains controversial, but recent ACC/AHA guidelines recommend 12 months for drug-eluting stents and 6 weeks for bare-metal stents.³⁰ The role for antiplatelet therapy remains a major question, but data suggest that cessation of recommended antiplatelet therapy in the perioperative period may have significant coronary thrombotic risks without major improvement in bleeding adverse events.^{35,36} The decision to stop antiplatelet therapy within 1 year of a drug-eluting stent or 6 weeks of a bare-metal stent placement should be made with caution. The continuation of aspirin therapy in patients with coronary stents was previously thought to increase the risk of bleeding. However, recent data and recommendations suggest that the continuation of single antiplatelet therapy with aspirin throughout the perioperative period even 1 year after stenting may be appropriate.³⁰

Congestive Heart Failure. CHF has been described as the single most important factor predicting postoperative cardiac morbidity.³⁷ All elective surgical procedures should be deferred until congestive failure is medically optimized. If surgery cannot be deferred, aggressive perioperative management is warranted with a goal of optimizing cardiac output. In contrast to isolated ischemic heart disease, CHF is more easily diagnosed by history, physical examination, and basic preoperative laboratory workup, including electrocardiography (ECG) and chest radiography. Because patients with left, right, or both left and right ventricular dysfunction are less tolerant

of the fluid shifts associated with surgery and the myocardial depression associated with the anesthetic, they constitute the highest-risk group for postoperative cardiac complications.

Pulmonary Disease

Pulmonary disease is classically divided into acute and chronic restrictive and obstructive disease. Restrictive disease is defined by processes that reduce lung volumes, and obstructive disease is characterized by reduced flow rates on pulmonary function tests.

Obstructive diseases are present in patients with forced expiratory volume in 1 second (FEV₁)/forced vital capacity (FVC) ratios of less than 50%. Obstructive pulmonary disease can be either chronic or acute (asthma). In either case, the reversible component of obstruction should be reversed before elective surgery. Patients are maintained on bronchodilator medications, and those with chronic secretions are appropriately hydrated and receive therapy to mobilize secretions. In patients with reactive airway disease, the endotracheal tube can induce severe bronchospasm. Even in patients who are well treated preoperatively, reactive bronchospasm can complicate anesthetic induction and the emergence from anesthesia. The principal method used to prevent or diminish this "foreign body"-induced bronchospasm is intubation of the patient at a deep level of anesthesia when reflexes are blunted.

The classic way to manage a patient with severe asthma is to induce with an agent that produces bronchodilation and to ventilate the patient with an inhalation agent until the patient is deeply anesthetized before performing laryngoscopy and intubation. The patient should be extubated while spontaneously ventilating but with the inhalation agent still in effect. The patient is brought back to consciousness while ventilating by mask. Unfortunately, this technique may not be feasible in patients who have a full stomach because of the risk of aspiration or who are difficult to intubate or ventilate.

Regional anesthetics can be useful in these patients for peripheral surgery or for procedures that require an anesthetic sensory level below T6. As the sensory and motor levels rise to T6 and above, patients lose significant accessory motor function that can decrease expiratory reserve volume and the ability to cough and clear secretions. Because of tenuous pulmonary status and the high incidence of postoperative pulmonary complications, these high-risk patients should be extubated with caution only when they meet adequate extubation criteria relative to preoperative test data. Changes in pulmonary mechanics and frequency of postoperative pulmonary complications are greatest after upper abdominal surgery. Both vital capacity and functional residual capacity are reduced, reaching lowest levels in the first 24 hours postoperatively. In the high-risk groups, therapy should be directed toward restoring functional residual capacity to preoperative levels. Such therapy improves compliance and gas exchange. Because of the potential adverse effects of systemic narcotics on respiratory drive, the use of epidural narcotics and local anesthetics for postoperative pain control is very popular. These techniques allow the patients to be extubated earlier and, in patients with intrathoracic and upper abdominal surgery, help restore pulmonary function toward preoperative values.³⁸

Obesity

Obesity causes a host of problems on both sides of the surgical drapes. Obesity is defined as a body mass index greater than or equal to 30 kg/m². Body mass index (BMI) can be easily calculated by dividing the patient's weight in kilograms by the square of his or her height in meters. The pathophysiologic changes associated with morbid obesity (BMI ≥ 40 kg/m²) affect the respiratory, cardiovascular, and gastrointestinal systems. Patients have an external restrictive disease that reduces functional residual capacity and worsens with the supine position. Breathing effort increases and ventilation becomes diaphragmatic and position dependent. Obese patients frequently desaturate at night and have a high incidence of sleep apnea. Because of increased blood volume and frequent desaturations, obese patients can develop pulmonary hypertension and right-sided heart failure. Obese individuals have a high incidence of coronary artery disease. Because of size alone, they have increased cardiovascular demands with limited cardiac reserve and exercise tolerance. Obese patients have a high incidence of hiatal hernia and gastroesophageal reflux, increasing the risk for aspiration on induction and emergence from anesthesia. Issues as mundane as venous access can cause significant problems in this patient group.

A significant concern of the anesthesiologist is gaining adequate control of the airway. The combined problems of aspiration risk, rapid desaturation caused by reduced functional residual capacity and increased oxygen demand, and technical difficulties associated with intubation due to anatomic fat deposits make intubation a high-risk procedure. If problems occur, there can be significant technical difficulties in obtaining a rapid cricothyrotomy. For these reasons, a nasal or oral awake intubation can be useful. Patients should receive prophylactic administration of H₂-receptor antagonists and a nonparticulate antacid to improve the pH of gastric contents. If intubations are to be done after induction of anesthesia, they

should be performed in a rapid sequence using cricoid pressure. To prevent aspiration on emergence, obese patients should be extubated when fully awake, preferably in the sitting position. Regional anesthetics can be very useful when peripheral procedures are planned. Unfortunately, morbidly obese patients can develop pulmonary failure just by lying flat, making it difficult to use epidural or spinal anesthetics for abdominal procedures. Epidural analgesics for postoperative pain management allow earlier extubation and ambulation of these patients.³⁸

Diabetes Mellitus

The incidence of diabetes mellitus (DM) is rising, particularly type 2 DM in the elderly. This is a systemic disorder that has particular relevance for the anesthesiologist and surgeon because of its effect on the vascular, renal, nervous, and immune systems. Patients with DM should be investigated for the presence of concomitant coronary artery disease, peripheral vascular occlusive disease, renal failure, and autonomic and peripheral neuropathy. Problems with cardiovascular instability, fluid balance, and aspiration due to gastroparesis should be expected. In addition, these patients are more prone to infection and have problems with temperature control. The management of the diabetic state in these patients is important and complicated. Hypoglycemia during the anesthetic state is a feared complication because of challenges in prompt diagnosis. Oral hypoglycemic agents such as glipizide should be stopped prior to surgery and hyperglycemic situations treated with short-acting intravenous or subcutaneous insulin during the perioperative period. Brittle diabetics, those prone to ketoacidosis or hypoglycemia, should probably be admitted the night before surgery or at least scheduled as the first case of the day. Insulin-dependent diabetics for same-day admission or outpatient surgery should take one half of their usual morning dose of long-acting insulin. After the establishment of an IV line, laboratory blood samples are drawn and infusion of dextrose is started. Additional insulin is then given according to the results of frequent (every 1 to 2 hours) blood sugar monitoring. Alternatively, simultaneous IV infusion of dextrose and insulin may be used to keep the blood sugar in the range of 120 to 180 mg/dL. Again, these patients, whenever possible, should be done as the first case of the day to interfere as little as possible with the diabetic regimen.

Renal Insufficiency and Failure

Because the kidneys play a vital role in metabolic, synthetic, and fluid management homeostasis, renal failure is associated with many effects on the cardiovascular, pulmonary, hematologic, gastrointestinal, and immune system. Preexisting renal insufficiency is a known risk factor for postoperative myocardial infarction and renal failure.^{39,40} Optimizing the fluid and metabolic status of a patient in end-stage renal disease is of vital importance. Elective surgery should be delayed until such optimization is performed. In emergent situations, the urgent need for hemodialysis should be considered intraoperatively or postoperatively to avoid life-threatening electrolyte and fluid derangements. Although postoperative renal failure has historically been the focus of cardiac surgery researchers, national data suggest that 1% of patients undergoing general surgery procedures will also experience postoperative acute kidney injury, with a sixfold rise in 30-day mortality. Risk factors for postoperative acute kidney injury in patients undergoing general surgery are listed in Table 12.11. These data should be considered during the patient consent process.

RISKS ASSOCIATED WITH REGIONAL TECHNIQUES IN PATIENTS BEING TREATED WITH LOW-MOLECULAR-WEIGHT HEPARIN

Low-molecular-weight heparin (LMWH) has become a routine method of prophylactically treating patients who are at risk for deep venous thrombosis. It has several advantages over traditional heparin and has therefore been adopted in Europe and the United States over the past few years. Unfortunately, there has been an increased number of reported cases of epidural hematoma formation when regional anesthetics are provided in patients who are being treated with LMWH.⁴¹ For that reason, the Society of Regional Anesthesia has published the following guidelines for central conduction block (spinal and epidural anesthesia) to try to minimize the incidence of this devastating complication:

1. The presence of blood during needle and catheter placement will require a delay of 24 hours, postoperatively, before initiation of LMWH therapy.

2. For patients on LMWH (once a day dosing), needle placement should occur at least 12 hours after the last LMWH dose. For patients receiving higher dosing (e.g., enoxaparin 1 mg/kg twice a day), placement should occur at least 24 hours after the last LMWH dose.
3. It is recommended that patients who have an indwelling epidural catheter will receive LMWH only when there is an extreme risk of deep vein thrombosis (DVT) and there is frequent monitoring of the patient's neurologic status (every hour); the catheter should not be removed within 12 hours of the last dose.
4. Following removal of an epidural catheter, LMWH dosing should not occur for at least 2 hours.⁴¹

PREOPERATIVE EVALUATION

- 9 The three goals of the preoperative evaluation are (a) to develop an anesthetic plan that considers the patient's medical condition, the requirements of the surgical procedure, and the patient's preferences; (b) to ensure that the patient's chronic disease is under appropriate medical therapy before an elective procedure; and (c) to gain rapport with and the confidence of the patient, answer any questions, and allay fears.

Optimally, to complete this task, an anesthesiologist would meet every patient before the planned surgical procedure to review the medical history, complete a physical examination, discuss the options and associated anesthetic risks, and develop an anesthetic plan. In the past, this was accomplished when the anesthesiologist visited the patient in the hospital the night before surgery. Currently, it is rare to have patients admitted the night before surgery even before the most comprehensive and complex surgical procedures. The evaluation must still be accomplished, but it must be done on an ambulatory basis, which creates associated logistical problems.

A patient's medical conditions should be optimized before an elective surgical procedure. This optimization is best performed by the primary care physician, with medical specialty consultation if necessary. If the procedure is deemed a surgical emergency, the anesthesiologist is responsible for assessing the patient quickly, developing the appropriate anesthetic plan, and proceeding to the operating room as soon as possible. In an emergency situation, the anesthesiologist is not obligated to seek medical consultation to evaluate chronic medical problems because time is essential. The following questions must be answered when evaluating a patient undergoing an elective surgical procedure (Table 12.12). What must be included in

TABLE 12.12**RESULTS****HOSPITAL MORTALITY RATES IN RELATION TO AGE, PREOPERATIVE DISEASE, AND SURGERY**

the preoperative evaluation? Second, who is involved in this process? When and where are all the steps in this process to be conducted? How should all the information be coordinated so that it is available to the appropriate personnel at the appropriate time?

The following steps must be completed before moving the patient into the operating room:

1. A comorbidity-focused history and physical examination
2. Appropriate laboratory studies and medical consultations
3. An anesthesiologist preoperative evaluation with assignment of an American Society of Anesthesiologists (ASA) physical status
4. Discussion with the patient of the options and risks
5. Development and communication of the anesthetic plan to the patient and surgeon
6. Acute optimization of any pertinent medical conditions

The history and physical examination have repeatedly been shown to be the most valuable parts of the preoperative assessment. It is primarily the surgeon's responsibility to obtain a basic history that includes current medical conditions, current medication, and previous surgical and anesthetic history. Questions that are of unique interest to the anesthesiologist are those that involve previous anesthetic problems experienced by the patient or blood relatives and the patient's exercise tolerance. This evaluation not only determines the laboratory tests that may be required but also allows for the assignment of ASA physical status (PS) (Table 12.13). The classification serves as a general measure of the patient's state of well-being, taking into account all problems the patient brings to the operating room, including systemic disturbances caused by the surgical illness. Although studies of anesthetic mortality show a correlation with the physical status classification, this categorization does not describe the risk directly. The risk of any operation is determined not only by patient-related factors but also by procedure-specific ones. For patients with complex medical problems, it is frequently helpful to supplement the surgical history and physical examination with a recent assessment by the patient's primary physician.

The value of preoperative laboratory studies has undergone substantial reevaluation since the mid-1980s. In the

past, a surgical procedure was an opportunity to obtain a battery of baseline laboratory tests, even for ASA PS-1 patients. The current thinking is that a laboratory test should not be ordered unless a change in the surgical or anesthetic plan is anticipated. The only preoperative screening test required at the University of Michigan, for instance, is an ECG within a year of the planned surgical procedure for men older than 40 and women older than 50 years of age. Pregnancy tests should be obtained only for women who state that they could be pregnant. For procedures with significant anticipated blood loss, a type and cross match is ordered, and a preoperative hematocrit is also required. All other tests should have an indication based on history and physical examination. A current strategy for selecting tests indicated by patient history is presented in Table 12.14. Electronic patient questionnaires have also been developed, allowing the appropriate laboratories to be selected based on the patient's response to questions.⁴²

Discussions of the options of anesthetic techniques and anesthetic risks are best performed by the anesthesiologist who will provide the anesthetic. If the surgeon prefers a specific anesthetic technique, this is best communicated directly to the anesthesiologist rather than recommended to the patient. The development of the anesthetic plan must be determined by the anesthesiologist.

The history, physical examination, and laboratory studies should be performed by the surgeon as soon as the surgical procedure is scheduled. The results of the laboratory studies must be evaluated well in advance of the day of surgery so that positive findings can be attended to in a timely manner. For healthy patients (ASA PS-1 and PS-2), the preoperative anesthetic assessment can be conducted by the anesthesiologist on the day of the procedure. If the patients have complex medical problems (ASA PS-3 or greater) or have significant concerns they want to discuss with an anesthesiologist, they should be evaluated before the day of surgery. Because of the logistical problems of scheduling, most institutions have developed preoperative anesthesia clinics where this process can take place. When specialty medical consultation is considered, the following questions should be answered. Does this patient have ischemic heart disease that requires further medical management

TABLE 12.13

CLASSIFICATION

PHYSICAL STATUS CLASSIFICATION OF THE AMERICAN SOCIETY OF ANESTHESIOLOGISTS

■ PHYSICAL STATUS CLASSIFICATION	■ DESCRIPTION
PS-1	A normal, healthy patient
PS-2	A patient with mild systemic disease that results in no functional limitation <i>Examples:</i> Hypertension, diabetes mellitus, chronic bronchitis, morbid obesity, extremes of age
PS-3	A patient with severe systemic disease that results in functional limitation <i>Examples:</i> Poorly controlled hypertension, diabetes mellitus with vascular complications, angina pectoris, prior myocardial infarction, pulmonary disease that limits activity
PS-4	A patient with severe systemic disease that is a constant threat to life <i>Examples:</i> Congestive heart failure, unstable angina pectoris, advanced pulmonary, renal, or hepatic dysfunction
PS-5	A moribund patient who is not expected to survive without the operation <i>Examples:</i> Ruptured abdominal aneurysm, pulmonary embolus, head injury with increased intracranial pressure
PS-6	A declared brain-dead patient whose organs are being removed for donor purposes
Emergency operation (E)	Any patient in whom an emergency operation is required <i>Example:</i> An otherwise healthy 30-year-old woman who requires dilation and curettage for moderate but persistent vaginal bleeding (PS-1E)

TABLE 12.14**SIMPLIFIED STRATEGY FOR PREOPERATIVE TESTING**

Estimated energy requirements for various activities			
1 MET	Can you take care of yourself? Eat, dress, or use the toilet? Walk indoors around the house? Walk a block or two on level ground at 2 to 3 mph or 3.2 to 4.8 km/h?	4 METs	Climb a flight of stairs or walk up a hill? Walk on level ground at 4 mph or 6.4 km/h? Run a short distance? Do heavy work around the house like scrubbing floors or lifting or moving heavy furniture? Participate in moderate recreational activities like golf, bowling, dancing, doubles tennis, or throwing a baseball or football?
4 METs	Do light work around the house like dusting or washing dishes?	>10 METs	Participate in strenuous sports like swimming, singles tennis, football, basketball, or skiing?

MET, metabolic equivalent.

or workup? Is medical treatment of these problems optimized? If not, what needs to be done and how long will it take?

In addition, the patient's medication regimen should be reviewed to ensure that appropriate medications are continued or discontinued in the days and hours leading up to an elective procedure. In general, diuretics and ACE-I/ARB medications should not be taken the day of surgery. Several important classes of medications should be continued per the patient's normal regimen: chronic pain therapy (including opioids), beta-blockers, statins, and proton pump inhibitors. The decision regarding anticoagulant therapy is a complex one that must take into account the indication for therapy, the likelihood and impact of surgical bleeding, and the risk of perioperative thrombosis. Insulin and oral hypoglycemic agents should be continued at a reduced dose given the fasting state of the surgical patient. Patients receiving chronic pain or opioid addiction therapy with buprenorphine (Subutex, Suboxone) can be particularly challenging to manage in the postoperative period and should be immediately referred to their primary care physician and an anesthesiologist to create a pain management plan prior to the day of surgery. Buprenorphine is mixed opioid agonist/antagonist that tightly binds at the μ receptor and has a long and varied half-life (24 to 60 hours). It can inhibit the analgesic benefits of traditional opioids in the postoperative period, resulting in uncontrolled pain, decreased patient satisfaction, and the potential for adverse events due to the need for very high doses of opioids.⁴³ A management protocol used at the University of Michigan is demonstrated in Algorithm 12.2.

An obvious problem that concerns anesthesiologists is the potential of a difficult intubation. This can be assessed as discussed earlier (see Fig. 12.1 and Table 12.8). Even if a patient has no medical problem, the possibility of a difficult airway warrants that the patient be seen preoperatively and evaluated. These patients can always be approached by an awake fiberoptic technique, but this takes planning and can cause a significant delay if there is no prior warning.

MONITORING THE SURGICAL PATIENT

One of the more obvious changes in anesthesia care has been the routine use of an array of electronic monitoring devices to provide continuous surveillance of physiologic status. Because the art and science of anesthesiology involves titrating pharmaco-

logic agents to produce desired physiologic effects, there must be a measured parameter to which drug dosages are titrated. Depending on the severity of preexisting disease and the extent and duration of the surgical procedure, invasive techniques can be used to provide comprehensive continuous data to guide the titration of fluid therapy and cardiovascular agents.

Monitors of Oxygenation

Pulse oximetry has been called the most significant advance in patient monitoring to date. This device continuously, non-invasively, and inexpensively provides arterial hemoglobin saturation (SaO_2) and peripheral pulse by measuring light absorption in a manner similar to that of a laboratory cooximeter. A laboratory cooximeter shines light through a cuvette filled with a blood sample. Each hemoglobin species absorbs light in direct proportion to its concentration (Beer-Lambert law). A cooximeter requires one wavelength of light for each hemoglobin species to be measured, that is, one wavelength for oxyhemoglobin and one for reduced hemoglobin. To measure other hemoglobins, such as carboxyhemoglobin or methemoglobin, the device requires four wavelengths of light.

The traditional pulse oximeter uses two wavelengths of light, one red and one infrared, that shine through a tissue bed, usually a finger. Opposite the light sources is a photodiode that measures the transmitted light intensity. A large proportion of the light absorbed as it passes through the tissues is not associated with arterial blood but with other components of the tissue, such as skin, muscle, bone, and venous blood. Therefore, the device analyzes only the pulsatile component of absorption and assumes that anything that pulses within the tissue bed is arterial blood, hence the name *pulse oximeter*. Actually, the pulse oximeter measures the ratio of the pulsatile component of red light absorbed to the pulsatile component of the infrared light absorbed. This ratio changes with SaO_2 . The exact relation between this ratio and SaO_2 has been empirically determined from volunteer studies and is programmed into the electronics of the oximeter. If any artifacts occur in a pulsatile nature, they may be erroneously integrated into the equation, causing erroneous SaO_2 estimates.

Several things should be remembered when interpreting a pulse oximeter's output. First, the device measures SaO_2 and not arterial oxygen tension (PaO_2). The PaO_2 must drop below 80 mm Hg before any significant change in SaO_2 occurs. As the PaO_2 drops below 60 mm Hg, the SaO_2 rapidly falls as the inflection point of the sigmoidal oxyhemoglobin

dissociation curve is approached. As a rough rule of thumb, as SaO_2 drops below 90%, the PaO_2 can be estimated by subtracting 30 points from the SaO_2 . For example, a SaO_2 of 85% corresponds to a PaO_2 of 55 mm Hg. Second, the pulse oximeter measures saturation (milliliters of oxygen per deciliters of blood) and not arterial content or oxygen delivery to tissues.

Because a traditional pulse oximeter uses only two wavelengths of light, it cannot detect the presence of carboxyhemoglobin (carbon monoxide poisoning) or methemoglobin. Recently introduced pulse oximeters incorporate additional wavelengths of light and are capable of detecting carboxyhemoglobin and methemoglobin.⁴⁴

Despite the potential drawbacks, the pulse oximeter has been shown to be impressively accurate in a wide variety of patients with a tremendous variation in pulse amplitude.⁴⁵

Ventilation Monitors

By definition, a patient is appropriately ventilated when arterial carbon dioxide tension (PaCO_2) is 40 mm Hg. Measuring the respiratory rate can document only the presence of ventilation, not its adequacy. Capnography, or end-tidal CO_2 monitoring, is the visual display of the CO_2 concentration at the airway. To understand the utility of capnography, one must understand dead-space components and how they affect CO_2 removal from the body.⁴⁶ Dead space (DS) is defined as the portion of the tidal volume (VT) that does not participate in gas exchange.

$$\text{VT} = \text{DS} + \text{VA}$$

The alveolar volume (VA) is the volume of the inspired gas that reaches well-perfused alveoli. The remainder of the VT, which equals the DS, can be divided into three subcomponents: apparatus dead space (DS_{ap}), anatomic dead space (DS_{an}), and alveolar dead space (DS_{al}). At the end of inspiration, the respiratory apparatus (e.g., endotracheal tube) is filled with inspired gas that should not contain CO_2 . Similarly, all the anatomic airways (trachea, bronchi, and all conducting airways down to the alveoli) should be filled with inspired gas and should therefore contain no CO_2 . In this model, there are two types of alveoli: those that are well perfused and those that are not perfused. The alveolar gas should completely equilibrate with the arterial blood and contain CO_2 at the same tension as the arterial blood; ideally, PaCO_2 should equal 40 mm Hg. As the patient expires, the CO_2 detected at the patient's mouth first reflects the DS_{ap} gas having no CO_2 ; followed by the DS_{an} gas, again with no CO_2 ; and finally the alveolar gases, containing both dead-space and well-perfused alveolar gas. When mixed alveolar gas reaches the airway, it produces a rapid rise in the CO_2 concentration to a level somewhere between the concentration in the alveolar gas (40 mm Hg) and the DS_{al} (0 mm Hg), depending on each component's proportion of volume. For example, if half of the alveoli are DS_{al} and PaCO_2 equals 40 mm Hg, then the plateau value of the capnogram should be 20 mm Hg, implying that half of the alveoli are not being perfused. With inspiration, the CO_2 value again drops to 0 until another expiration, and a square wave appears again as the alveolar gas is detected at the mouth. With each breath, there should be a square wave, whose height approaches the PaCO_2 value as the amount of the DS_{al} gas approaches 0.

In a healthy young adult, there is no significant DS_{al} gas, and the end-tidal CO_2 value equals the PaCO_2 . Therefore, the difference between these values indicates the proportion of DS_{al} in the patient. The presence of a capnogram itself implies that there is metabolism (the production of CO_2), circulation (blood flow to the lungs), and ventilation (respiratory rate and an intact ventilator circuit).

Providing this information on a breath-to-breath basis, the continuous capnogram is extremely useful in many critical

situations. It can be used as a surveillance monitor of both the respiratory circuit and the cardiovascular system. Any acute decrease in cardiac output will decrease blood flow to the lungs and increase the DS_{al} , causing an acute drop in end-tidal CO_2 . For this reason, the device was originally used during neurosurgical procedures in the sitting position to detect the presence of air emboli. This principle also allows the detection of pulmonary emboli or any acute drop in cardiac output. In fact, the only acute catastrophic cardiopulmonary problem that will not be detected by the capnometer is arterial desaturation. Therefore, the combination of the capnometer and the pulse oximeter creates a dynamic duo for beat-to-beat and breath-to-breath surveillance of metabolism, circulation, ventilation, and oxygenation.

Circulation Monitors

Hemodynamic stability can be monitored by a variety of methods, the most basic of which is systemic arterial blood pressure. Intermittent, noninvasive measurement of systemic blood pressure with an oscillometric blood pressure cuff is the standard in the operating room, and its accuracy equals that of clinical measurements by auscultation. Blood pressure cuffs can be cycled as quickly as once per minute, but when used for an extended duration, they should be cycled no more than once every 3 to 5 minutes. When tighter control or observation is required in patients with significant comorbidities or large swings in hemodynamics due to surgical circumstances, invasive arterial monitoring is used. Although pressure measurements provided by invasive techniques are different from those of noninvasive techniques, they usually coincide closely. A continuous invasive arterial tracing can also be used to assess the adequacy of fluid resuscitation by following the systolic pressure variation (SPV) with positive-pressure ventilation. As positive-pressure ventilation impedes venous return within a closed thorax, decreases in systolic pressure associated with a respiratory pattern can be detected. In patients with sinus rhythm with stable cardiac contractility, the degree of SPV reflects the intravascular volume status of the patient. The normal range of SPV is 5 to 10 mm Hg. A systolic pressure decrease of greater than 10 mm Hg during positive-pressure ventilation implies inadequate preload and the need for more aggressive fluid resuscitation.⁴⁷

In this context, central venous access may be reserved for patients and procedures with the potential for large, rapid volume resuscitation requirements. Transesophageal echocardiography (TEE) is now commonly used to assess cardiac function. This technique is easily used in the anesthetized, intubated patient and can quickly assess systolic and diastolic function as well as valvular dysfunction. Increasing familiarity in the use of TEE by noncardiac anesthesiologists may result in the pulmonary artery catheter being reserved for very specific patients demonstrating the need for pulmonary artery pressure monitoring or continuous cardiac output trending.

“Awareness” and Level of Consciousness Monitors

When delivering a general anesthetic, one of the major imperatives is to achieve and maintain a loss of consciousness. Normally, this is achieved through careful observation of vital signs (heart rate, blood pressure), physical examination signs (movement in a patient without neuromuscular blockade), and delivery of inhalational or intravenous agents at doses consistent with a loss of consciousness. However, this “science” is inexact and must account for patient age, comorbidities, chronic medications, surgical stimulus, and patient-to-patient

variability. As a result, patients may rarely experience “awareness under anesthesia”—a state characterized not only by consciousness but also by recall of intraoperative events. The laypress and public have increased their scrutiny of this perioperative event.

First, appropriate expectations and effective communication of the anesthetic are required. Recent literature has demonstrated that patients undergoing regional anesthesia are as likely to report unpleasant “awareness” as patients undergoing a general anesthetic.⁴⁸ This is despite the reality that loss of consciousness is only a goal of general anesthesia. Clearly, anesthesiologists must communicate the anesthetic plan and expectations more accurately.

Second, several level of consciousness monitors have been developed in hopes of providing the anesthesiologist with additional objective data to guide their assessment and actions. The current generation of monitors generally uses electroencephalographic (EEG) analysis to provide the clinician with an assessment of the relative “depth” of anesthesia achieved. Several commercially available monitors such as the bispectral index (BIS) from Aspect Medical Systems and Entropy from General Electric Healthcare are in common clinical use. Data evaluating the value of these EEG-based monitors in reducing awareness are conflicting, with several large trials producing varying results.^{49,50} As a result, the ASA has not adopted awareness monitors as a standard of care and leaves the decision to use such monitoring technology to each provider, patient, and situation.⁵¹ Further large, randomized studies comparing EEG-based monitoring techniques to routine clinical care in a typical general surgery population are currently under way and may provide valuable data.

COMMON PROBLEMS IN THE POSTOPERATIVE PERIOD

Postanesthesia care units are required in any setting where surgical procedures are conducted. The increased scope of surgery and the invasive technology used to monitor sicker patients has increased the service and training required to operate these facilities. In 1994, the ASA revised the 1988 Standards for Postanesthesia Care (Table 12.15).

The scoring systems used to assess the postoperative patient direct attention to the primary areas of concern. The postanesthesia recovery score is an attempt to evaluate postanesthesia patient status⁵² (Table 12.16). This basic information should be incorporated in a record that provides clear documentation of postoperative events. Documentation should also include details of postoperative outpatient care, with a note indicating postoperative telephone contact made to elucidate problems. Problems should receive appropriate follow-up, and written postoperative discharge instructions should be provided for the patient.

Investigators have reported that 24% of patients experience a postanesthesia care unit complication. Nausea, vomiting, and the need for airway support constitute 70% of these complications⁵³ (Fig. 12.2). The need to maintain airway support was by far the most common respiratory complication. The duration of the procedure as well as ASA classification and type of procedure had a significant bearing on the incidence of complications in this study. Hypothermia was also a common problem that prolonged postoperative postanesthesia care unit stay (Fig. 12.3). Hypothermia has the deleterious effects of altering drug metabolism and delaying recovery. Furthermore, it causes shivering, which increases the metabolic demand for oxygen.

Among cardiovascular complications in the postoperative period, none is more important or more difficult to diagnose than myocardial ischemia. The association of perioperative

myocardial ischemia with cardiac morbidity has been clearly documented.²⁵ In a series of high-risk patients undergoing noncardiac surgery, researchers noted that “early postoperative myocardial ischemia is an important correlate of adverse cardiac outcomes.”²⁵ Diagnosis is complicated by the fact that only 10% to 30% of patients suffering documented myocardial infarction have pain and that postoperative ECG T-wave changes are often nonspecific.⁵⁴ Instead, one must seek secondary indications of ongoing ischemia or “angina equivalents,” such as hypotension, arrhythmias, elevated filling pressures, or postoperative oliguria. Arrhythmias are common and are significant primarily because of the association with myocardial ischemia or hypoxemia.

Nausea and vomiting are rarely unifactorial and cause considerable discomfort to patients. Opioids are responsible for stimulating the emesis center in a significant cohort of patients. These patients may provide a clear history of opioid sensitivity and anesthetic and analgesic regimens may be tailored to limit the exposure of these patients to these drugs. In general, however, there is little evidence to favor one anesthetic or anesthetic technique over another, although propofol appears to have an antiemetic effect. Nitrous oxide, often considered causative, does not appear to increase the incidence of nausea according to well-documented studies. It is not unusual for an antiemetic agent to be included preoperatively or as part of the anesthetic technique, especially in patients with a positive history or those deemed to be at risk, such as menstruating young women undergoing laparoscopy. Standard usage includes phenothiazines, butyrophenones, 5HT₃ antagonists, and steroids. A multimodal approach that avoids redosing of a given medication class has been demonstrated to be most beneficial.⁵⁵ Despite decades of research, classic medications such as droperidol remain a mainstay of therapy. The FDA recently added a black-box warning to droperidol due to concerns of QT prolongation, but such concerns have not been validated when compared to other perioperative medications; as a result, many institutions continue to use droperidol for postoperative nausea and vomiting prophylaxis.^{56,57}

The most common cause of delayed emergence is the residual effects of anesthesia. The differential diagnosis of delayed emergence is best approached by ruling out physiologic, pharmacologic, and neurologic cases, in this order (Table 12.17). There should be little confusion about the implication of muscle relaxants because physical indications of ventilatory distress, combined with the readings of the blockade monitor, should clearly indicate the role of these drugs. Where appropriate, opioids can be reversed using titrated doses of naloxone. Flumazenil can be used for reversal of benzodiazepines.

POSTOPERATIVE ACUTE PAIN MANAGEMENT

Postoperative pain is an inevitable consequence of surgery. Its severity is site dependent (Table 12.18), but the magnitude of the pain experienced by individual patients after similar surgical procedures is influenced by a multitude of factors. Variation in patient experience has been clearly demonstrated by several authors and is reflected in deficiencies in postoperative pain control.⁵⁸ The recognition of this clinical problem has prompted interest in underlying pain mechanisms and in innovative ways to alleviate postoperative suffering.

In 1965, the crucial role of nociceptive C fiber feedback behavior and its modulation by cells in the substantia gelatinosa of the dorsal horn was recognized.⁵⁹ Repetitive stimulation of these fibers by cellular mediators, such as kinins and catecholamines, promotes neural excitation, prolongs repetitive firing, and lowers the threshold to further excitation. As a

TABLE 12.15**STANDARDS FOR POSTANESTHESIA CARE**

■ STANDARDS		■ CRITERIA TO BE FULFILLED
Standard I ^a	All patients who have received general, regional, or monitored anesthesia care shall receive appropriate postanesthesia management.	<ol style="list-style-type: none"> 1. A PACU or an area that provides equivalent postanesthesia care shall be available to receive patients after anesthesia care. All patients who receive anesthesia care shall be admitted to the PACU or its equivalent <i>except</i> by specific order of the anesthesiologist responsible for the patient's care. 2. The medical aspects of care in the PACU shall be governed by policies and procedures that have been reviewed and approved by the department of anesthesiology. 3. The design, equipment, and staffing of the PACU shall meet requirements of the facility's accrediting and licensing bodies.
Standard II	A patient transported to the PACU shall be accompanied by a member of the anesthesia care team who is knowledgeable about the patient's condition. The patient shall be continually evaluated and treated during transport with monitoring and support appropriate to the patient's condition.	
Standard III	On arrival in the PACU, the patient shall be reevaluated and a verbal report provided to the responsible PACU nurse by the member of the anesthesia care team who accompanies the patient.	<ol style="list-style-type: none"> 1. The patient's status on arrival in the PACU shall be documented. 2. Information concerning the preoperative condition and the surgical/anesthetic course shall be transmitted to the PACU nurse. 3. The member of the anesthesia care team shall remain in the PACU until the PACU nurse accepts responsibility for the nursing care of the patient.
Standard IV	The patient's condition shall be evaluated continually in the PACU.	<ol style="list-style-type: none"> 1. The patient shall be observed and monitored by the methods appropriate to the patient's medical condition. Particular attention shall be given to monitoring oxygenation, ventilation, circulation, and temperature. During recovery from all anesthetics, a quantitative method of assessing oxygenation such as pulse oximetry shall be employed in the initial phase of recovery. This is not intended for application during the recovery of the obstetric patient in whom regional anesthesia was used for labor and vaginal delivery. 2. An accurate written report of the PACU period shall be maintained. Use of an appropriate PACU scoring system is encouraged for each patient on admission, at appropriate intervals prior to discharge, and at the time of discharge. 3. General medical supervision and coordination of patient care in the PACU should be the responsibility of an anesthesiologist. 4. There shall be a policy to ensure the availability in the facility of a physician capable of managing complications and providing cardiopulmonary resuscitation for patients in the PACU.
Standard V	A physician is responsible for discharging the patient from the PACU.	<ol style="list-style-type: none"> 1. When discharge criteria are used, they must be approved by the department of anesthesiology and the medical staff. They may vary depending on whether the patient is discharged to a hospital room, to the ICU, to a short stay unit, or home. 2. In the absence of the physician responsible for the discharge, the PACU nurse shall determine that the patient meets the discharge criteria. The name of the physician accepting responsibility for discharge shall be noted on the record.

ICU, intensive care unit; PACU, postanesthesia care unit.

result, C fibers do not show fatigue, and the stage is set for continuous pain. Counterirritation of large afferent activity has been shown empirically to have beneficial effects. The gate-control theory provides an explanation for the inhibition of C fiber-mediated pain. Serotonergic and enkephalinergic descending inhibitory pathways modulate activity in the dorsal horn before information is relayed to the somatosensory cortex through the spinothalamic tract. The common observation that pain is worse at night, when less sensory information is processed, and that it decreases with

daytime activity is an example of how this complex neural system functions.

Superficial somatic pain is well localized and has a protective function. Superficial somatic pain is readily treated by common analgesic techniques. Deep somatic pain may not be well localized; may have some protective function, as in joint immobilization; and is fairly responsive to a variety of analgesics. Visceral pain, served almost entirely by C fiber activity, is poorly localized, often referred, and difficult to treat. In major operations, all modes can be activated, compounding the clinical challenge of providing adequate pain management. These clinical observations direct the focus of postoperative pain management to the treatment of somatic pain by attacking the nociceptor and the subsequent transmission of the painful impulse by the nerve fiber. The use of

nonsteroidal anti-inflammatory drugs with or without the injection of local anesthetics into the wound is very effective. If done preemptively at the time of surgery, this approach can significantly benefit the patient's postoperative experience.⁶⁰ Examples of nerve blocks for various procedures are shown in Figure 12.4.

Including potent opioids in the treatment of deep pain, both somatic and visceral, has been routine. However, the responses to standard regimens have been notoriously unreliable, from inadequate pain relief to narcosis, with complications at both ends of the scale. It was not until the 1980s that variations in response were linked to variable serum concentrations of analgesic drugs. Interpatient variation in serum levels to any standard dose can be fivefold, and interpatient therapeutic concentrations can vary on a similar scale. When factored together, there is the potential for a 25-fold variation in patient response to a standard drug prescription. Each patient has an individual therapeutic window. The clinical implications are enormous.

In 1968, investigators demonstrated the virtue of small IV doses given on demand.⁶⁰ As a result, the patient experienced greater pain relief, yet used the same or less total narcotic. Although there was significant patient variation, the demand from any individual patient, though cyclic, was constant. Patient-controlled analgesia (PCA) and the technologic and administrative systems to provide it have developed to a point of some sophistication, requiring servicing and a support structure with its own set of problems (Table 12.19). PCA administration requires a receptive environment, education of

Failure to deliver on demand
Defective one-way valve at Y-connector
Faulty alarm system
Device malfunctions

all personnel, and adequate patient instruction. PCA has received widespread acceptance by patients, nursing staff, and physicians because it provides more prompt and painless analgesia that more closely matches the patient's need over time. PCA is as safe as conventional IM medication. Morphine and meperidine are commonly used drugs, and an example of orders is shown in Table 12.20.

Transdermal narcotic delivery is receiving attention and may become available for postoperative pain. The method is both practical and inexpensive and aims to maintain continuous delivery and constant blood levels. Fentanyl has been the drug of choice and has been well received by patients. The method appears to be safe, but there is a significant lag time between application and the attainment of therapeutic blood levels.

The discovery of endorphins in the 1970s and recognition of their importance in modulating pain at spinal sites led to the supposition that it would be possible to selectively apply opioids directly to receptors. This led to the development of epidural opiate analgesia, in which opioids are applied directly to the receptors at spinal sites. The goal of epidural analgesia is to obtain maximal analgesia while minimizing systemic side effects. For severe acute postoperative pain caused by major surgery, epidural analgesia has proved to be a superior modality

TABLE 12.20

EXAMPLE OF ORDERS FOR PATIENT-CONTROLLED ANALGESIA (PCA)

1. Patient is to be initiated on PCA with standard monitoring protocol.		
2. Drug selection	Morphine 1 mg/mL	Hydromorphone 0.2 mg/mL
3. Loading initial dose (start PRN for pain)	2–5 mg	0.2–0.5 mg
Maximum total loading dose	10 mg	1 mg
4. Pump setting PCA dose	1–2 mg	0.1–0.2 mg
Lockout interval	6–10 min	6–10 min
4-Hour limit	30–45 mg	4–5 mg

University of Michigan Hospitals online order form Acute Pain Service, Patient Controlled Analgesia Standard Orders.

TABLE 12.21**OPIOID PROTOCOLS IN EPIDURAL OPIATE ANALGESIA**

	■ MORPHINE ^a	■ FENTANYL ^b
Length of onset	Longer (30–60 min)	Shorter (15–30 min)
Duration	Longer (6–24 h for single bolus)	Shorter (1–2 h for single bolus)
Cephalad spread and side effects	More prone	Less prone
Indication	Favored for lumbar administration after abdominal surgery	Favored for thoracic administration after chest surgery
Dose	Typically 3–5 mg, q6–8h	Typically 50–75 mg/h (±dilute bupivacaine)

^aHydrophilic: slow in, slow out.
^bLipophilic: fast in, fast out.

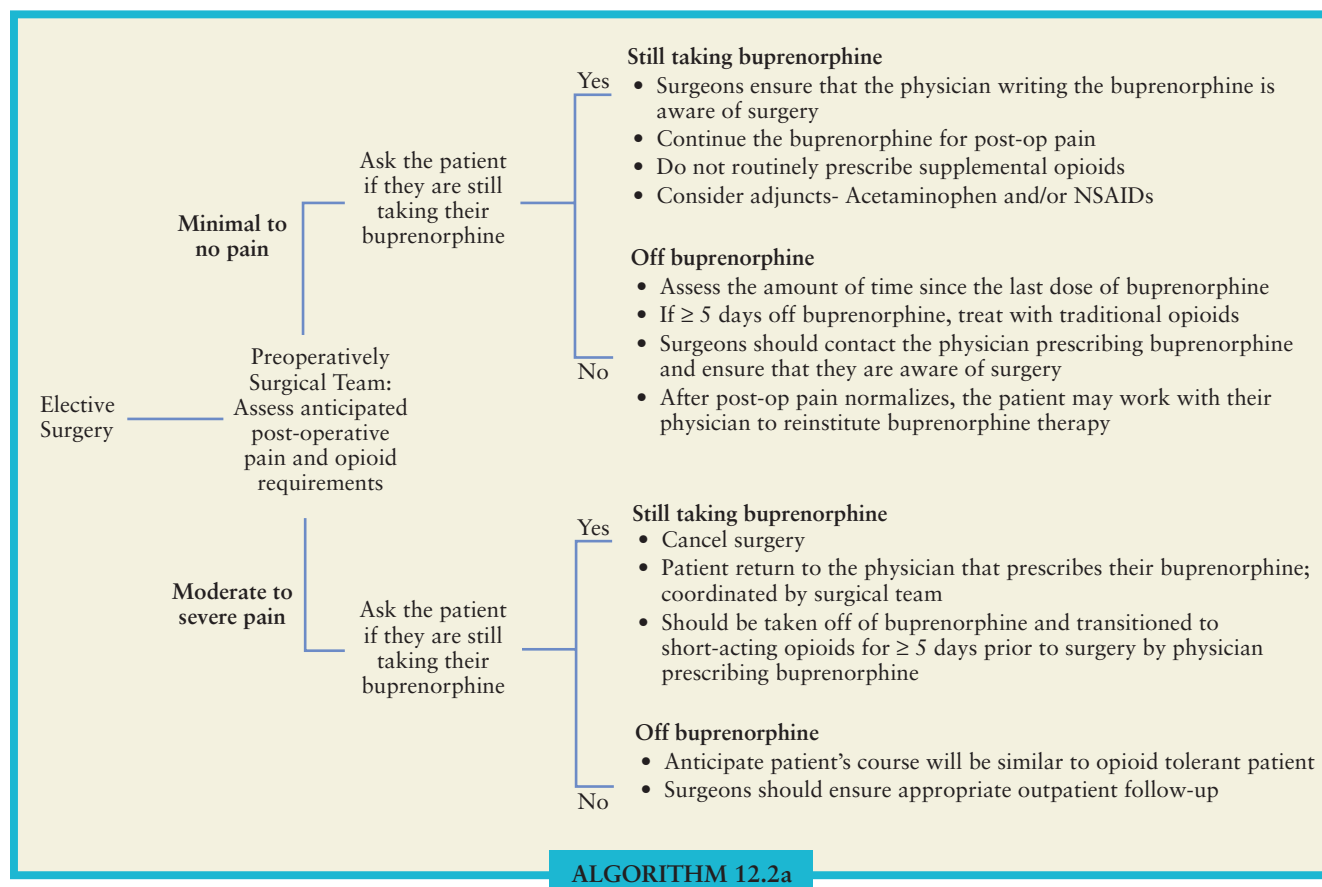

for pain control. In high-risk cases, there is evidence that it has an overall beneficial effect on morbidity.³⁸

The effective use of this sophisticated modality requires education and the establishment of protocols with rigorous attention to detail. The potential for respiratory depression demands adherence to monitoring standards. Morphine and fentanyl, often in combination with a dilute local anesthetic solution, are most often prescribed. A typical order form with monitored parameters is shown in Table 12.21.

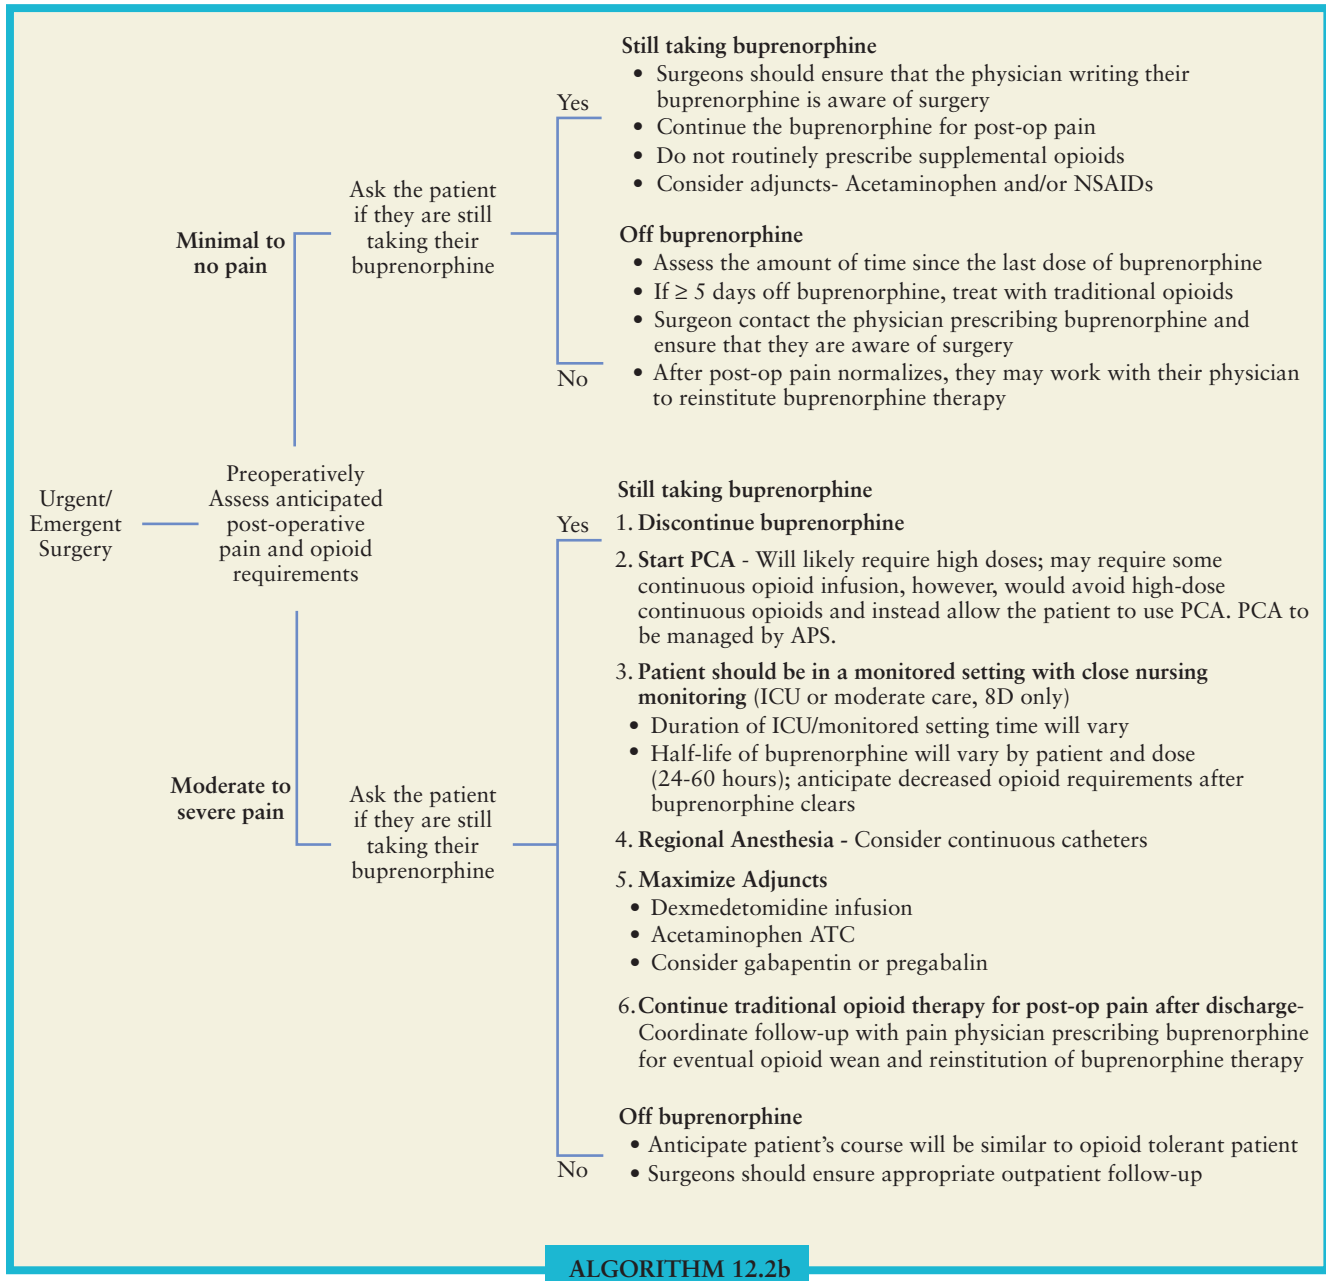

A comprehensive postoperative pain management service demands resources and must use the physical and pharmacologic modalities available while recognizing the significant subjective component of any individual's pain problem. The ability to recognize the impact of acute pain or an underlying

chronic pain disorder requires that experience be brought to bear on difficult problems. The active involvement of nursing staff and surgeons is essential for the patient to achieve maximal benefit. It is incumbent on the pain-management service to render efficient, continuous, and cost-effective care.

12 Postoperative acute pain management may require a multimodal approach that incorporates opioids, peripheral nerve blockade, and nonopioid analgesics. Chronic pain patients can be particularly difficult to manage and may require preoperative optimization by an anesthesiologist. These patients require very large doses of IV analgesics and need to be maintained orally. The best way to evaluate an appropriate starting dose is to convert the preoperative opioid regimen to an IV morphine equivalent then add what would be required to treat

ALGORITHM 12.2. Algorithm for managing a patient on chronic buprenorphine therapy. APS, acute pain service; ICU, intensive care unit; PCA, patient-controlled anesthesia; NSAIDs, nonsteroidal anti-inflammatory drugs. (continued)

ALGORITHM 12.2. (Continued)

the acute surgical pain (see Table 12.4). The use of nonopioid and nonpharmacologic treatments is essential in the management of acute postoperative pain in this patient population. Peripheral nerve blockade, aggressive use of acetaminophen and nonsteroidal anti-inflammatory agents, and novel agents such as dexmedetomidine may be necessary to minimize the adverse effects associated with uncontrolled postoperative pain. As mentioned earlier, these patients may need to be evaluated by an anesthesiologist prior to the day of surgery. This should be an institutional requirement for patients on chronic buprenorphine therapy, as demonstrated in Algorithm 12.2.

CHAPTER 13 ■ CANCER

STEVEN K. LIBUTTI

KEY POINTS

- 1 There are six important capabilities that a cell or a group of cells must acquire to be capable of growing, invading, and metastasizing and thus becoming a cancer: (a) self-sufficiency in growth signals, (b) insensitivity to antigrowth signals, (c) evading apoptosis, (d) limitless replicative potential, (e) sustained angiogenesis, and (f) tissue invasion and metastases.
- 2 The ability of a cell to become self-sufficient in its growth and no longer rely on the normal temporal sequences of programmed cell growth is often the result of mutations in the genes involved in growth regulation and control.
- 3 Transformation from the normal phenotype to invasive malignancy appears to involve a loss of normal tumor suppressive and growth inhibitory responses as well as the acquisition of inappropriate proliferative signals.
- 4 Angiogenesis is necessary for tumor growth and progression and is a potential site for targeted molecular therapy.
- 5 Gene therapy and immunotherapy for cancer are areas of active investigation that have not yet reached standard practice.
- 6 Operative resection or regional therapy of metastatic disease can be helpful for patients.

Few medical diagnoses carry with them the fear and dread that a diagnosis of cancer brings to the patient. Historically, Hippocrates is credited with first distinguishing between benign and malignant tumors. Hippocrates described invasive carcinoma using the Greek term for crab, *karkinos*, based on the similarities between the invasive tongue of solid tumors and the claws of the crab. *Karkinos* forms the root for the term *carcinoma*. The word *cancer* is derived from the Latin, *cancrium*, for crab.

The term has come to represent a constellation of malignant processes involving a host of tissue types, each with differing potentials for invasion and metastases. Each pathologic type of cancer has different approaches for its diagnosis and management. However, there are certain basic characteristics that define the transition from normal cell division and proliferation into abnormal, unregulated growth and invasion, which is the hallmark of cancer. The breadth and depth of information regarding the processes involved in the development, diagnosis, and treatment of cancer are complex; this chapter gives an overview to provide a basis for further investigation and discovery.

EPIDEMIOLOGY

The earliest recorded writings related to cancer were made in the Edwin Smith Papyrus in Egypt around 1600 BC. Since that time and throughout recorded history, references are made to various malignancies of the bone and soft tissue that were attributed to sources as varied as vital humors and parasites. Cancer affects approximately 9.6 million Americans, and a total of 1.4 million new cancer diagnoses and 570,000 cancer-related deaths are expected in the United States in the year 2008. For persons younger than the age of 85, cancer is the leading cause of death in the United States and has been since 1999. Although overall mortality rates from cancer have declined in both men and women, the rate of decline in deaths due to heart disease has been much more rapid (Fig. 13.1).

Between 1995 and 2004, the cancer incidence rates in men stabilized, while the incidence rates in women have stabilized between 1999 and 2004. The overall death rate due to cancer has continued to decrease in men since 1990 and in women since 1991. Cancers differ in men and women by both type and incidence. The most common cancers in men by incidence

are prostate (25%), lung and bronchus (15%), and colon and rectum (10%). In women, the most common cancers by incidence are breast (26%), lung and bronchus (14%), and colon and rectum (10%). In both men and women, lung and bronchial cancers continue to account for the largest number of cancer-related deaths (31% men; 26% women). This is followed by prostate cancer in men (10%) and breast cancer in women (15%) accounting for the second most common histologies resulting in death. Colon and rectal cancer remains the third most common cause of cancer-related deaths in both men (8%) and women (9%) (Table 13.1). Although the overall incidence of cancer, as well as mortality due to cancer, decreased between 1994 and 2008, for several tumor types there has been either an increase in incidence or relatively little change over that time. For example, melanoma of the skin increased in incidence among men from 3% to 5% and among women from 3% to 4% between 1994 and 2008. The incidence of thyroid cancer increased from 2% to 4% between 1994 and 2008 for women, in whom thyroid cancer occurs more frequently than in men (3:1). Despite the decline in incidence and associated death among common cancer types in both men and women, cancer continues to pose a significant cost to the United States in both human and financial terms.

In 2003, cancer cost the United States an estimated \$189.5 billion. Roughly one third of these costs were due to direct medical costs, and more than two thirds were related to non-medical costs, including lost productivity and lost workdays. The Centers for Disease Control and Prevention (CDC) has estimated that cancer screening and early detection could reduce colorectal cancer deaths by 30%, breast cancer deaths by 16%, and cervical cancer deaths by 60%. Further, it is estimated that in the year 2003, more than 180,000 cancer deaths were due to the consequences of tobacco use. Although the connection between cigarette smoking and lung cancer is an obvious and well-established one, smoking plays a role in approximately 30% of all other cancer deaths (e.g., kidney, oral, bladder). As newer and more effective adjuvant therapies, most notably, biologic agents, are developed and validated, these costs will undoubtedly increase.

Major efforts are under way in cancer prevention. Some causative agents, such as tobacco, are obvious. Other factors that influence the development of cancer include genetic predisposition, diet and exercise, and environmental factors. For

FIGURE 13.1. Age-adjusted death rates from cancer and heart disease. (Jemal A, et al. *CA Cancer J Clin* 2008;58:71–96.)

several cancer types, environmental influences have a complex interaction with other known and unknown factors leading to the development of the disease. For example, chronic hepatitis (both hepatitis B and hepatitis C) increases the incidence of hepatocellular carcinoma, but not all patients with hepatocellular carcinoma have chronic hepatitis, and not all patients with chronic hepatitis develop hepatocellular carcinoma. The relationship of cervical cancer to human papillomavirus (HPV) infection is well established. Estimates for the impact of screening demonstrate that reducing the transmission of HPV could have a significant impact on reducing the incidence of cervical cancer. Recently, a new vaccine for HPV was developed at the National Cancer Institute (NCI) and approved for use in women. A program of early vaccination for at-risk individuals will hopefully lead to a decreased incidence of cervical cancer. Sun exposure (or artificial ultraviolet [UV] light exposure) influences the incidence of melanoma skin cancer; however, melanoma can develop in patients without a significant history of sun or UV exposure. Although some genetic factors, such as mutations in the *BRCA1* or *BRCA2* genes, significantly increase the risk of developing breast cancer, the majority of patients with breast cancer have no such germline mutations. More work is needed to understand the complex interactions of genetics and environment on the cell to better identify avoidable risk factors. This may help to prevent the development of cancer.

ETIOLOGY

At its most basic, cancer can be defined as abnormal cell growth. Often described as a foreign invader in the body, it is more accurate to think of cancer as the body's own cellular

growth machinery gone wrong. Throughout history, a variety of theories emerged in an attempt to explain the findings of abnormal tissue growth and invasion. Hippocrates ascribed the formation of cancer to an excess of black bile (one of the four humors or body fluids) collecting in various body sites. This theory was unchallenged through the Middle Ages. In the 18th century, John Hunter was a proponent of the concept that cancer derived from the lymph system. The notion was that tumors arose from lymph, which is constantly expressed by the blood.

In the 19th century, Yohans Mueller dispelled the lymph theory by demonstrating that cancer was made up of cells. However, Mueller did not believe that cancer arose from normal cells but rather from “budding elements” (blastema) that arose between normal tissues. This theory was later rejected by Mueller's student Rudolph Virchow, who demonstrated that all cells, including cancer cells, had their origin from other cells. Virchow proposed that chronic irritation led to the formation of cancer and that cancers could spread through tissues like a fluid. The idea that cancer resulted from irritation and trauma persisted into the 20th century.

Modern thinking recognizes a series of important events that are required for a cell to become cancerous and to grow, invade, and metastasize. Hanahan and Weinberg described six important capabilities that a cell or a group of cells must acquire to be capable of growing, invading, and metastasizing and thus becoming a cancer. These six properties are as follows (Fig. 13.2):

1. Self-sufficiency in growth signals
2. Insensitivity to antigrowth signals
3. Evading apoptosis
4. Limitless replicative potential
5. Sustained angiogenesis
6. Tissue invasion and metastases

TABLE 13.1

THE 10 LEADING CANCER TYPES FOR THE ESTIMATED NEW CANCER CASES AND DEATHS, BY GENDER, FOR THE UNITED STATES IN 2008

■ MALES			■ FEMALES		
■ CANCER	■ INCIDENCE		■ CANCER	■ INCIDENCE	
ESTIMATED NEW CASES ^a					
Prostate	186,320	(25%)	Breast	182,460	(26%)
Lung and bronchus	114,690	(15%)	Lung and bronchus	100,330	(14%)
Colon and rectum	77,250	(10%)	Colon and rectum	71,560	(10%)

All sites	294,120	100%	All sites	271,530	100%

^aExcludes basal and squamous cell skin cancers and in situ carcinoma except urinary bladder. Estimates are rounded to nearest 10. Adapted from Jemal A, et al. *CA Cancer J Clin* 2008;58:71–96.

FIGURE 13.2. Acquired capabilities of cancer. (Adapted from Hanahan D, Weinberg R. The hallmarks of cancer. *Cell* 2000;100:57.)

Each of these capabilities is placed in the perspective of current research efforts in the sections that follow.

CANCER BIOLOGY

The basic unit of tissues and organs is the cell. The control of cell growth and differentiation is the focal point in understanding the processes involved in malignant transformation. Cells normally grow, divide, perform necessary functions to maintain homeostasis, and die in a programmed fashion throughout most tissues and organs. A cancer cell is one that has alterations in this carefully controlled program that lead to the phenotype of cancer. Hanahan and Weinberg's model describes four of the six functional capabilities, which directly relate to changes within the cell itself. These are the acquired ability for self-sufficient growth, insensitivity to antigrowth signals, ability to evade apoptosis, and limitless replicative potential. The other two functional capabilities—sustained angiogenesis and tissue invasion and metastases—involve changes not only within the individual cancer cell but also in the interaction and relationship with other host elements.

Oncogenes and Tumor Suppressor Genes

- 2 The ability of a cell to become self-sufficient in its growth and no longer rely on the normal temporal sequences of programmed cell growth is often the result of mutations in the genes involved in growth regulation and control. Activating mutations of proto-oncogenes create oncogenes. For example, a point mutation of a single nucleotide in the *ras* gene can result in cell-transforming activity. Approximately one half of human colon cancers have a mutation in the *ras* oncogene.

The three Ras proteins (h-, k-, and n-ras) are members of a large superfamily of Ras-related proteins that share significant structural homology as well as guanosine triphosphatase (GTPase) activity. All known *ras* genes include an identical nine-amino-acid domain in the N-terminal half of the protein. This undergoes a conformational shift when Ras binds to GTP. These Ras-related proteins function as molecular switches, involved in the control of a variety of cellular functions including growth, organization, and transport. The biologic activity of Ras is controlled by a number of factors known as guanine nucleotide exchange factors that promote the formation of the active GTP-bound state (e.g., SOS), and the GTPase-activating proteins (e.g., NF1-GAP) that promote formation of the inactive guanosine diphosphate (GDP)-bound state. Structural mutations involving codons 12, 13, and 61 result in mutant Ras proteins that lack this GTPase activity. These oncogenic Ras proteins are locked in the active GTP-bound conformation, leading to constitutive activation of downstream targets. This can be thought of as an “on-off” switch for cell growth that is locked in the “on” position due to the mutation in the *ras* oncogene. In addition to stimulating growth signals, mutant Ras proteins can also facilitate survival signals within the cell, allowing the cell to evade programmed cell death.

Oncogenes can also be activated through chromosomal rearrangements known as translocations that involve the transfer of one segment of a chromosome to another. The resulting shift in position of genes can change the way in which those genes are regulated. An example of this is the Philadelphia chromosome that appears in chronic myelogenous leukemia (CML). This chromosomal rearrangement results when the small *c-abl* proto-oncogene is translocated from chromosome 9 to the small *bcr* locus on chromosome 22. The result of this creates the small *bcr/abl* oncogene. This oncogene leads to an increase in tyrosine kinase activity and therefore downstream signaling in the cell, leading to uncontrolled cell growth.

Oncogenes also affect the development of familial endocrine tumors. An activating mutation of the RET proto-

oncogene on chromosome 10 causes the development of medullary thyroid cancer in patients suffering from multiple endocrine neoplasia (MEN) 2a and MEN 2b. Patients with MEN 2 uniformly develop medullary thyroid cancer, and many also develop other tumors (such as adrenal pheochromocytomas) due to the constitutive activation of this gene.

Another class of genetic change that predisposes to cancer, both sporadically and within inherited cancer syndrome families, is inactivating mutations of tumor suppressor genes. Tumor suppressor genes typically code for proteins that play an important role in cellular growth control. When these genes are mutated, growth dysregulation can occur. In the familial setting, these mutations inactivate one allele of a growth control gene in the germline. An inactivating mutation of the second allele of the gene in a susceptible cell causes loss of the growth control function in that cell, contributing to the development of the characteristic tumor. Tumors that develop sporadically due to mutations of tumor suppressor genes require accumulation of inactivating changes in both copies of the gene within a single cell. This explanation of tumor suppressor genes is known as the Knudsen hypothesis. Examples of this include mutations of the *BRCA1* or *BRCA2* genes, which together account for 75% of familial breast cancer cases. *BRCA1* acts as a tumor suppressor gene in that mutation of one copy followed by inactivation of the second copy of the gene in a cell results in malignant transformation. Another example of a tumor suppressor gene is the *MEN1* gene that is inactivated in MEN type 1, the *vHL* gene inactivated in von Hippel-Lindau syndrome, and the adenomatous polyposis coli (*APC*) gene locus that can lead to the development of colorectal cancers when mutated.

Myc Regulation of Cellular Differentiation

In human neoplasia, many components of the dedifferentiated phenotype appear to involve regulation by helix-loop-helix motif (HLH) proteins. At least three major pathways have been identified that impact on HLH-regulated cellular differentiation. These include amplification/overexpression of the *c-myc* proto-oncogene, overexpression of Id transcriptional repressors, and activation of Notch signaling. With respect to Myc, the *c-myc* proto-oncogene is amplified in many human tumors, including lung cancer, breast cancer, cervical cancer, and ovarian cancer. In addition, increased expression of *c-myc* is noted in up to one third of breast and colon carcinomas. *c-myc* appears to represent a central switch through which a number of oncogenic pathways including BCR-ABL, b-catenin, and *c-src* converge to stimulate neoplasia (Fig. 13.3). *c-myc* impacts many cellular events relevant to neoplasia including proliferation, apoptosis, adhesion, immortalization, and differentiation. These effects appear to be mediated primarily through formation of heterodimers with the class IV HLH factor Max, leading to activation of Myc target genes (Fig. 13.4). Both during normal development and during neoplastic transformation, Myc/Max heterodimers appear to inhibit expression of differentiation-related genes.

Inhibition of Differentiation by Notch Signaling

Another major pathway influencing HLH-regulated cellular differentiation involves the Notch signaling pathway. Notch signaling appears to play a critical role in regulating cellular differentiation during both normal development and malignant transformation. The pathway is highly conserved, with homologous components in *Caenorhabditis elegans*, *Drosophila*, zebrafish, mice, and humans (Table 13.2). Four human Notch family members have been identified. Notch proteins

FIGURE 13.3. The *c-myc* gene is a central oncogenic switch for oncogenes and the tumor suppressor adenomatous polyposis coli (APC). The APC tumor suppressor protein mediates the degradation of β -catenin. The Wnt oncoprotein is shown activating its receptor, which results in the stabilization of free β -catenin, which sustains activating mutations in human cancers; β -catenin is a cofactor for the transcription factor Tef. Tef activates *c-myc* expression through specific DNA binding sites. The oncogenic fusion protein TEL-PDGFR hypothetically activates *c-src*, as does native PDGFR, resulting in the activation of *c-myc*. The BRC-ABL oncoprotein likewise requires *c-myc* for its activity. (Adapted from Dang CV. *c-Myc* target genes involved in cell growth, apoptosis, and metabolism. *Mol Cell Biol* 1999;19:1.)

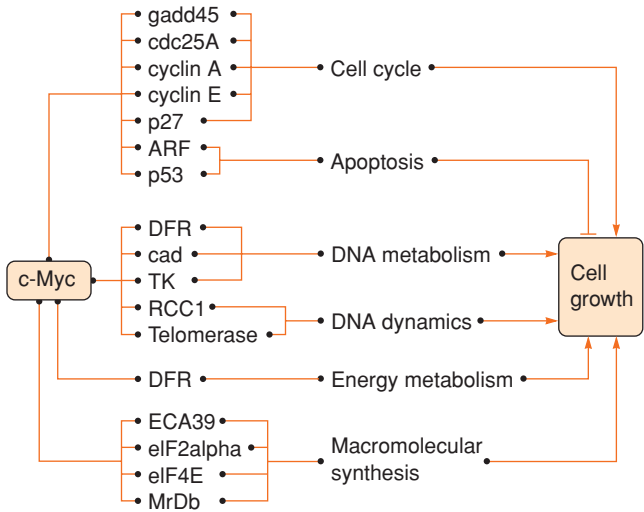

FIGURE 13.4. Links between *c-Myc*, selected putative target genes, cellular functions, and cell growth. The diagram illustrates the complexity of the connections between *c-Myc* and its putative target genes, which are shown clustered according to their functions. The various cellular functions cooperate to promote cell growth. It should be noted that this diagram does not reflect the controversies over the authentication of the various target genes. (Adapted from Dang CV. *c-Myc* target genes involved in cell growth, apoptosis, and metabolism. *Mol Cell Biol* 1999;19:1.)

FIGURE 13.5. Notch signaling inhibits lineage-specific cellular differentiation. Ligands presented by adjacent differentiated cells lead to Notch receptor activation. Following intramembrane cleavage of Notch by γ -secretase, the intracellular domain of Notch (Notch-IC) translocates to nucleus and cooperates with RBP-J κ (mammalian homologue of *Drosophila Suppressor of Hairless*) to induce HES-1. HES-1 represses transcription of lineage-specific transcription factors, including neurogenin 3, myoD, and the achaete-scute homologue (ASH). Activation of Notch signaling thereby maintains cells in an undifferentiated, stem cell-like state.

are transmembrane receptors containing extracellular tandem epidermal growth factor (EGF)-like repeats as well as three Lin/Notch repeats that function in ligand binding and Notch activation. As transmembrane receptors, Notch proteins are unique in apparently lacking any enzymatic activity. Instead, Notch proteins undergo proteolytic cleavage on activation by binding to DSL ligands (e.g., Delta, Serrate, Lag-2). Recent data suggest that proteolytic cleavage of Notch may be accomplished by γ -secretase, an enzyme also responsible for proteolytic production of β -amyloid from amyloid precursor protein. Following proteolytic cleavage, the Notch intracellular domain (Notch-IC) is released to interact with a number of cytoplasmic and nuclear proteins, including CSL proteins such as *Drosophila Suppressor of Hairless* and mammalian CBF-1. Interactions between Notch-IC and CSL proteins result in transcriptional activation of Hairy/Enhancer of Split (HES) class VI HLH protein. Once bound to DNA, HES proteins recruit a corepressor known as Groucho, thereby preventing expression of a number of cell lineage-specific class II bHLH proteins, including MyoD, neurogenin 3, and achaete-scute homologues (Fig. 13.5).

Notch signaling therefore represents a mechanism to prevent lineage-specific cellular differentiation. During development, this function plays a critical role in lateral inhibition as well as in boundary formation. Notch signaling is also implicated in various forms of neoplasia. Notch-IC is capable of transforming rat kidney cells in cooperation with adenoviral E1A and substitutes for activated ras in this assay. Notch receptors and ligands are upregulated in human cervical cancer, and activating translocations involving Notch family members have been identified in acute T-cell leukemia. Notch also appears to be required for immortalization of B lymphocytes by Epstein-Barr virus and represents a site for activating integration by the mouse mammary tumor virus. Additional studies have identified an important role of the Notch target gene HES-1 in regulating differentiation status in non-small cell lung cancer.

Telomerase and Cell Immortalization/Senescence

Senescence is the process during which a normal cell ages and dies. This process is controlled, in part, by specialized hetero-

chromatic structures at the ends of eukaryotic chromosomes called telomeres that function to stabilize and protect the chromosome. During normal somatic cell replication, telomeres become progressively shorter with each cell division, resulting in chromosome instability. It has been postulated that the shortening of telomeres represents a checkpoint mechanism by which cellular senescence is signaled in normal replicating cell populations.

Telomerase is an RNA-dependent DNA polymerase that stabilizes telomeres by synthesizing the six oligonucleotide repeat TTAGGG. This stabilization can allow indefinite replication and thus "cell immortalization." Although inactive in most somatic cells, telomerase remains activated in germ cells and lymphocytes. A unique characteristic of the cancer cell is immortality with the ability to divide repeatedly without undergoing normal cellular senescence. A correlation between telomerase and cancer has recently been documented by the detection of telomerase activity in a high percentage of primary human malignancies including cancer of the lung, colon, breast, and prostate. By remaining in the activated state, telomerase may contribute to the uncontrolled replicative capacity of the cancer cell. This finding has stimulated much discussion of the potential diagnostic, prognostic, and therapeutic implications of telomerase in the management of cancer.

Cell Survival/Programmed Cell Death

Virtually all cell populations are controlled through a balance of cell survival and cell death. Under certain conditions, such as terminal differentiation, growth factor deprivation, or DNA damage, survival signals to the cell are overtaken by death signals. Cell death can occur in a variety of forms, but the most common forms of cell death are necrosis and apoptosis. Necrotic cell death takes place primarily from noxious stimuli to the cell due to chemical or heat exposure, ischemia, or other insults. In contrast, apoptosis, or programmed cell death, occurs via a complex, genetically determined process. Apoptosis is a continual process in many normal as well as altered cell populations. For instance, during embryogenesis, organ formation occurs through a series of remodeling events that include apoptosis. Apoptosis is also an active process in many disease states. Following myocardial infarction, induction of apoptosis can occur in the damaged cardiac muscle cells.

The process of apoptosis is described as a cascade of events, each mediated by intracellular proteins, ultimately leading to apoptotic cell death. After receiving a cell death stimulus, induction of genes that promote apoptosis occurs, thereby shifting the intercellular balance toward proteins with proapoptotic activity. Two of the best-studied apoptotic genes are *Bcl-2* and *Bax*. Normally, the levels of antiapoptotic *Bcl-2* allow for continued cell survival. During the apoptotic state, *Bcl-2* levels are downregulated, shifting the balance toward proapoptotic proteins such as *Bax*. Downstream regulators of the apoptotic cascade are recruited including endonucleases, which cleave chromatin, resulting in nuclear fragmentation. This results in the formation of apoptotic bodies and other morphologic characteristics of apoptosis such as cell shrinkage and loss of contact with adjacent cells. In contrast, necrotic cell death is characterized by cellular swelling and ultimate rupture of the cell membrane. Just as apoptosis is active in embryogenesis and the molding of organ structure and function, it is also important in disease states such as cancer. In general, cancer cells that are resistant to cell death have altered their balance of apoptotic regulators. For instance, cancer cells that are resistant to conventional therapies such as radiation and chemotherapy often have increased levels of antiapoptotic proteins such as *Bcl-2*. To change the balance toward apoptotic cell death, some newer therapies attempt to upregulate proapoptotic proteins such as *Bax* or, conversely, downregulate antiapoptotic proteins such as *Bcl-2*.

In addition to the induction of apoptosis by these proteins, programmed cell death can also occur via recognition events of the immune system. Specifically, the Fas antigen (CD-95, APO-1) is a cell surface protein of the tumor necrosis factor (TNF) family. When stimulated by its ligand (FasL) under certain conditions, Fas-bearing cells can undergo apoptotic cell death. This is a possible mechanism of cytotoxic T-cell- and natural killer cell-mediated death as well as other autoimmune responses.

Abnormal Growth Regulation in Cancer

- 3 Transformation from the normal phenotype to invasive malignancy appears to involve a loss of normal tumor suppressive and growth inhibitory responses as well as the acquisition of inappropriate proliferative signals. The presence of inappropriate proliferative signals has been well documented in most malignancies and includes overexpression of peptide growth factors (transforming growth factor β [TGF- β], amphiregulin, heparin-binding EGF) and of growth factor receptors (e.g., HER2/neu). Alternatively, there may be mutational activation

of the signal transduction pathways for the growth factors (e.g., *ras* and *src* oncogenes), activation of oncogenes that are directly involved in stimulating progression of the cell cycle regulation (*myc*, *cyclin D1*, etc.), or inactivation of genes that provide checkpoint control on cell cycle progression (e.g., the retinoblastoma gene *p53*).

Cell Cycle Regulation in Cancer

The cell cycle involves cellular events controlling replication of chromosomal DNA during the S phase and the separation of replicated chromosomes during cell division (mitosis or meiosis, M phase). The cell cycle is an indispensable process for survival of an organism and is highly conserved throughout evolution. The S phase and M phase are separated by gap periods, or G phases. The G1 phase precedes the S phase and the G2 phase precedes the M phase (Fig. 13.6). G0 describes cells that are in a nonreplicating, quiescent state. G0 cells are often differentiated cells that may be metabolically active, but are not involved in the process of cellular replication. The cell has mechanisms for responding to extracellular signals to recruit G0 cells into the cell cycle.

The process of cell cycle progression is tightly regulated. The factors responsible for advancing cell cycle progression were initially described in yeast and in amphibian eggs. Cyclins were discovered as proteins that oscillated during specific periods of the cell cycle. Subsequent work led to the identification of the catalytic partners of the cyclins, called cyclin-dependent kinases (CDKs). Specific sets of cyclins with their partner CDKs drive progression through specific periods of the cell cycle (Fig. 13.7). Mistakes in DNA replication or in chromosomal segregation are detected and prevented from propagation. This function, termed *cell cycle checkpoint control*, involves regulation of the levels and activities of the cyclins and CDKs and also involves the regulation of programmed cell death (apoptosis).

Quiescent cells may be recruited to the cell cycle by mitogenic stimulation (e.g., growth factor exposure). Normal cells depend on exogenous mitogenic stimulation only during the first two thirds of the G1 phase. At this two-thirds point, also called the restriction (R) point, the cell may commit itself to advance into the S phase and subsequent phases of the cell cycle (Fig. 13.8). The retinoblastoma protein (pRB) is the molecular switch that controls passage through the R point. Unphosphorylated or hypophosphorylated pRB blocks R point transition, whereas phosphorylation of pRB prevents it from blocking cell cycle progression.

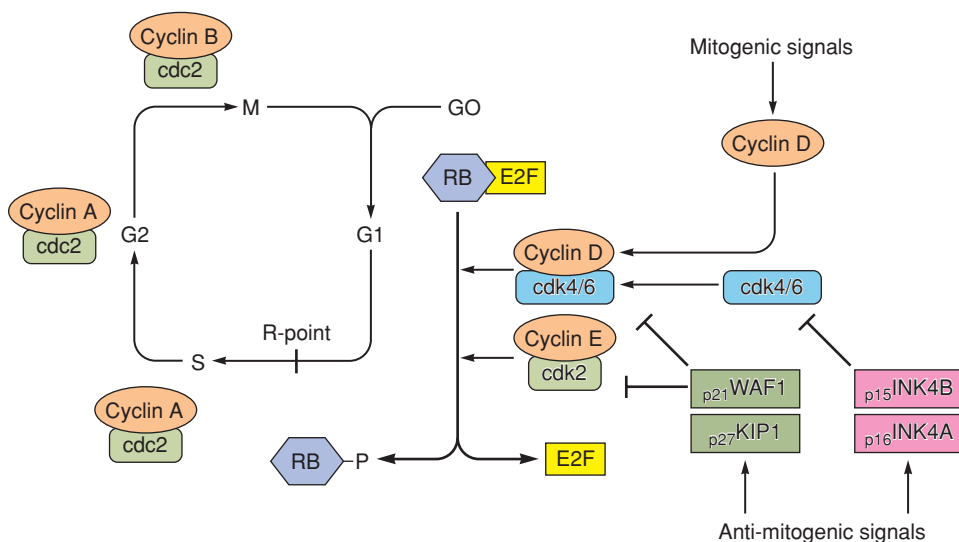

FIGURE 13.6. The cell cycle clock machinery. G0, M, G1, S, and G2 refer to the quiescence, mitosis, first gap, DNA synthesis, and second gap phases of the cell cycle, respectively. The restriction point (R-point) is shown preceding S-phase entry. RB and RB-P represent unphosphorylated and hyperphosphorylated forms of the retinoblastoma protein. (Adapted from Lundberg AS, Weinberg RA. Control of the cell cycle and apoptosis. *Eur J Cancer* 1999;35:531.)

FIGURE 13.7. The cell cycle clock. This version of the cell cycle shows where the retinoblastoma protein (pRb) is either phosphorylated or dephosphorylated to regulate cell cycle transit.

Expression of a specific subset of the cyclins called D-type cyclins (D1, D2, and D3) is increased in early to mid-G1 in response to mitogenic signals. The D-type cyclins assemble with their catalytic partners, CDK4 and CDK6, and the cyclin D-CDK complex enters the cell nucleus where it becomes phosphorylated by a CDK-activating kinase (CAK). A critical function of the cyclin D-dependent kinases is the phosphorylation of the Rb protein. Growth factor activation of Ras signaling and the MAPK cascade induces transcription of the cyclin D1 gene, decreases the turnover of the cyclin D1 protein, and regulates cyclin D-CDK assembly. Expression of the D-type cyclins is dependent on continuous mitogenic stimulation. Progression through the mid- to late G1 phase of the mammalian cell cycle is dependent on the cyclin D-dependent protein kinases.

Cyclin D-dependent kinases initiate the phosphorylation of Rb in mid-G1, and then subsequent activation of the cyclin E-CDK2 complex leads to further phosphorylation of Rb on additional sites. Cyclin A-dependent CDK (CDK2) becomes activated during the S phase and cyclin B-dependent CDK (CDK2) becomes activated during G2 and M. These cyclin-dependent kinases help to maintain Rb in a hyperphosphorylated state until mitosis has been completed and Rb is returned to its hypophosphorylated state at the beginning of G1. Hypophosphorylated Rb inhibits the transcriptional activity

of E2F protein family members. Hyperphosphorylation of Rb in late G1 phase disrupts its association with E2F family members, thereby enabling them to express their activity as transcription factors. The activation of the E2F transcription factor complex is required for the expression of a set of genes whose activities are required for S-phase progression. These include gene products that regulate nucleotide metabolism and DNA synthesis, as well as cyclins E and A.

The activities of CDKs are governed by other proteins called CDK inhibitors (CKIs). There are two families of CKIs based on structure and their CDK targets. One class includes the INK4 proteins (inhibitors of CDK4), which specifically bind and inhibit the activities of CDK4 and CDK6. This family is composed of four such proteins (p16^{INK4a}, p15^{INK4b}, p18^{INK4c}, and p19^{INK4d}). The Cip/Kip family comprises the other family of CKIs. This family includes the proteins p21^{Cip1}, p27^{Kip1}, and p57^{Kip2}. The CKIs of the Cip/Kip family were originally thought to interfere with the activities of cyclin D-, cyclin E-, and cyclin A-dependent kinases. This view has now evolved with further data confirming that the Cip/Kip proteins are potent inhibitors of cyclin E- and cyclin A-dependent CDK2 activity; however, this family of CKIs appears to act as positive regulators of cyclin D-dependent kinases. Increased levels of cyclin D/CDK4 during the G1 phase results in sequestration of the Cip/Kip CKIs, thereby preventing them from associating with and inhibiting cyclin E- and cyclin A-dependent CDK2. Activated CDK2 catalyzes hyperphosphorylation of Rb and also triggers the proteolytic destruction of p27^{Kip1}.

In addition to transcriptional activation and induction of cyclin gene expression, proteolysis is a critical function in the regulation of the cell cycle. As mentioned previously, proteolytic destruction of p27^{Kip1} is triggered during the S phase. Once the S phase has been initiated, the cell is no longer reliant on mitogenic signals or the D-dependent cyclins for progression through the remainder of the cell cycle. Cyclin E is degraded as cells progress through the S phase, cyclin A is degraded during G2, and cyclin B is degraded by the completion of the M phase to reset the system and thereby reestablish a period of mitogen dependence in the next G1 phase (Fig. 13.9).

Disruption of the growth suppressive function of Rb is a common event in cancer. This may occur as the result of mutational inactivation of Rb itself or because of the disruption of p16 function. Increased expression and activation of cyclin D and CDK4 (via amplification or transcriptional activation) are also common events in human cancer and result in the same type of inactivation of growth inhibitory function of Rb. Interestingly, complete loss of Cip/Kip function has not been

FIGURE 13.8. Interactions of the retinoblastoma protein (pRb). The interaction of pRb and E2F is regulated by cell cycle-dependent phosphorylation by specific cyclins acting with their partner cyclin-dependent kinases. Underphosphorylated pRb forms stable complexes with E2F/DP heterodimers and this complex actively represses transcription. pRb becomes hyperphosphorylated in late G1, thereby releasing E2F/DP, which is transcriptionally active when unbound from pRb. Late in the S phase, DP becomes phosphorylated, thereby neutralizing the DNA-binding capability of the E2F/DP heterodimer. (Adapted from Kaelin W/G Jr. Functions of the retinoblastoma protein. *Bioessays* 1999;21:950.)

FIGURE 13.9. Fluctuations of cyclins and cyclin kinase inhibitors during the cell cycle. Cyclins E, A, and B undergo periodic oscillation during each cell cycle. In contrast, the D-type cyclins tend to remain elevated in cycling cells under the influence of growth stimuli. Levels of the inhibitor $p27^{Kip1}$ tend to remain high in quiescent cells but are decreased in proliferating cells. (Adapted from Sherr CJ. Cancer cell cycles. *Science* 1996;274:1672.)

observed in cancer nor have cyclin E gene amplification or mutations resulted in increased cyclin E-dependent CDK activity.

The CKIs appear to function as checkpoint controls to ensure that cell cycle progression occurs under the proper environmental conditions and that the proper intracellular signaling has been completed prior to the initiation of DNA synthesis. Further checkpoints are the DNA damage and replication controls that block mitosis when DNA is damaged or DNA replication is incomplete. These checkpoint controls are essential for maintaining genomic stability, the failure of which allows cells to divide when DNA is damaged or DNA synthesis is incomplete or in the presence of faulty chromosomal segregation.

All cancer cells have abnormalities in one or more of the components of cell cycle control involved in G₁- to S-phase transition. In some cases, loss of Rb function itself is the event that releases the cells from extracellular signaling constraints. Mutational loss of Rb function occurs in the vast majority of retinoblastomas and less frequently in other tumor types such as lung cancers and soft tissue sarcomas. In the absence of functional Rb protein, E2F is active and there is no requirement for activation of cyclin D/CDK4 to initiate DNA synthesis. Amplification of the cyclin D1 gene is common in several types of human tumors such as breast, head and neck, esophageal, and hepatic malignancies. Increased expression of cyclin D1 without gene amplification is common in colorectal cancer. Deletion of the $p16^{INK4a}$ gene is also common in human cancers, particularly in melanomas and in a subset of pancreatic cancers. Hereditary loss of $p16^{INK4a}$ function is associated with increased risk for melanoma and pancreatic cancer. All of the previous defects in cell cycle regulators result in loss of the same G₁/S checkpoint control. It is rare for more than one of the previously mentioned defects to be identified in the same tumor.

Genomic Instability in Cancer

Genomic instability, with a high frequency of chromosomal loss and gain, genome doubling, and subtler genetic mutations, is a common characteristic of cancer cells. Genomic instability increases the chance of specific gene mutations that are ultimately responsible for the various phenotypes of cancer cells. Cancer cells acquire defects in the checkpoints that control normal mitosis, with its equal distribution of chromosomes into daughter cells and cytokinesis. Failure of this checkpoint may result in unequal distribution of chromosomes or failure to undergo cytokinesis, and either polyploidy (4N, 8N, etc.) or aneuploidy.

The tumor suppressor protein p53 plays a critical role in maintaining genomic stability. p53 function is required to initiate checkpoint-activated cell cycle arrest and programmed cell death in response to DNA damage. This function of p53 is necessary to ensure the integrity of the cellular genome by protecting it from the adverse effects of DNA damage. The p53

protein functions as an important transcription factor mediating expression of a variety of genes whose products may directly regulate growth arrest or apoptosis. Growth arrest induced by p53 may enable a cell to repair DNA that has been damaged. Alternatively, p53 also functions to induce apoptosis to prevent propagation of a cell lineage containing mutated DNA sequences.

Expression of p53 may be induced by either DNA damage or by inappropriate mitogenic signaling. An example of an important p53-responsive gene product involved in cell cycle arrest is the cyclin kinase inhibitor protein $p21^{Cip1}$. Several p53-responsive gene products appear to be involved in the apoptotic response. These include Bax, Fas/Apo, Killer/Dr5, and the redox regulator gene products known as PIGs (p53-induced genes). The expression of Mdm2 is also induced on activation of the p53 gene. Mdm2 is a negative feedback regulator of p53 whose function is to target p53 for rapid degradation. Interestingly, one of the two products of the *INK4a/ARF* locus, $p14^{ARF}$ inhibits the function of Mdm2, thereby stabilizing and activating p53 and promoting cell cycle arrest and apoptosis in response to inappropriate mitogenic signals. The other product of the *INK4a/ARF* locus is $p16^{INK4a}$, the important inhibitor of CDKs 4 and 6, and a mediator of G₁ cell cycle.

The protein product of the *Myc* proto-oncogene also regulates both cell proliferation and apoptosis in cell culture systems. *Myc* expression is capable of preventing cells from exiting the cell cycle and of promoting continuous cell cycle progression. Expression of *Myc* also inhibits differentiation in certain cell types. Similar to the situation in which inappropriately increased E2F triggers apoptosis, inappropriate *Myc* expression can also trigger apoptosis. Both increased E2F and *Myc* increase the expression of the ARF protein ($p14$ and $p19$), and as described previously, increased expression of ARF stabilizes p53, leading to both growth arrest and apoptosis.

There is a growing list of additional proteins that are involved in sensing and repairing DNA damage, or in ensuring correct chromosomal segregation during mitosis. Loss of function of these important genomic “caretaker” systems appears to be common in cancer cells, and this loss facilitates genomic instability with the accumulation of additional genetic lesions. The cumulative genetic mutations lead to tumor cells with selective advantages for aggressive biologic behavior including invasiveness and metastatic capacity, resistance to immunosurveillance, resistance to apoptosis, and the ability to resist cancer therapeutic interventions.

Loss of Growth Inhibitory Effects of Transforming Growth Factor β in Cancer

TGF- β regulation of epithelial cell proliferation is altered by transformation. Loss of responsiveness to the growth inhibitory effects of TGF- β occurs in many cancer cell types, including pancreatic, breast, and colorectal carcinoma cells. Thus, loss of growth inhibitory responses to TGF- β appears to

FIGURE 13.10. The effect of the transforming growth factor β (TGF- β) signaling pathway on cells is context dependent. Normal cells respond to TGF- β with growth inhibition and TGF- β appears to function as a tumor suppressor under normal conditions. Although complete loss of the TGF- β receptors is expected to eliminate all autocrine (but not paracrine) effects of tumor-derived TGF- β , postreceptor mutations should not. Tumor cells often lose the ability to undergo growth arrest in response to TGF- β . Despite this loss of growth inhibitory effect, TGF- β autocrine effects on cell morphologic change and cell adhesion and cell migration (all likely to be advantageous for tumor cells) appear to be retained along with the paracrine effects.

be a common and important event that attends malignant transformation of epithelial cells (Fig. 13.10).

Transforming Growth Factor β Signaling Abnormalities in Cancer

The association of colorectal cancers, pancreatic carcinomas, and breast cancers with genetic lesions in the TGF- β signal transduction pathway underscores the importance of TGF- β in maintaining homeostasis in the digestive tract and in the breast. One of the mechanisms by which tumor cells become resistant to the growth inhibitory actions of TGF- β is through downregulation or mutation of TGF- β type II receptor (T β RII). Loss of TGF- β receptor function causes cellular loss of negative growth regulation by TGF- β . Several studies have suggested that a decrease in expression or inactivation of T β RII is a key step for the neoplastic transformation of epithelial cells in both the breast and the colon. Activation of Ras protein, which occurs frequently in colorectal cancer, results in a decreased expression of the T β RII.

T β RII inactivation has been detected in a subgroup of colorectal carcinomas associated with the microsatellite instability or RER (replication error) phenotype identified in approximately 13% of all colorectal cancers. Recent studies have also confirmed the presence of T β RII mutations in an additional 15% of microsatellite stable (MSS) colon cancers and TGF- β signaling abnormalities distal to T β RII in an additional 55% of these MSS colon cancers. It is of interest and seemingly paradoxical that the subset of colorectal cancers that exhibit microsatellite instability (and T β RII mutations) tend to be proximal colon cancers and have a better prognosis (stage for stage) than the majority of sporadic colorectal cancers that do not share these genetic defects.

Mutational loss of function of TGF- β signal transduction proteins has been identified in human colorectal cancer. Madr2 (Smad2) mutation was observed in 4%, and DPC4 (Smad4) mutation has been reported in up to 30% of human colorectal cancers. Also, loss of heterozygosity (LOH) of Smad3 has been detected in 2 (one sporadic and one HNPCC) of 17 cancers examined. These types of mutations may have a significantly different phenotypic outcome as compared with that resulting from loss of the T β RII. Smad4 mutation has also been identified in familial juvenile polyposis, a syndrome

characterized by a predisposition to hamartomatous polyps and gastrointestinal cancer. These studies suggest that disruption of Smad signaling may be involved in either the initiation or progression of certain cancers.

Transforming Growth Factor β as a Tumor-promoting Factor

There are several lines of evidence that TGF- β may actually promote malignant transformation and tumor progression for several different cell types and under selected circumstances. TGF- β expression tends to be increased in a wide variety of cancers (including colon cancer) relative to adjacent normal tissues. Transformation of cells with dominant oncogenes (e.g., Ha-*ras* or *v-src*) activates transcription of the TGF- β 1 gene. Studies of human colorectal cancers have demonstrated that high-level expression of TGF- β in the primary tumor is associated with advanced stages and is an independent predictor of risk for recurrence and decreased survival.

There are several potential mechanisms for this tumor-promoting effect. For example, TGF- β may suppress tumor immunosurveillance. TGF- β exhibits growth inhibitory effects on moderate to well-differentiated primary colon carcinomas but stimulates the proliferation and invasion of poorly differentiated and metastatic colonic carcinomas. Treatment with TGF- β can induce estrogen-independent tumorigenicity of human breast cancer cells. TGF- β treatment can also substitute for wounding as a promoter of fibrosarcomas in chickens infected with the Rous sarcoma virus.

Transformation of preinvasive epithelial neoplasm to the invasive phenotype with metastatic potential is characterized by several profound changes in gene expression and in cellular and tissue morphology. The changes in cellular morphology and tissue architecture can be observed histologically and are accompanied by dramatic changes in the behavior of the transformed cells. The metastatic phenotype is associated with the acquisition of fibroblastoid features and the ability of the cells to invade stroma and blood vessels. There is mounting evidence that autocrine TGF- β expression by tumor cells can play a major role in the epithelial to fibroblastoid conversion that accompanies malignant transformation in mammary cells and in keratinocytes. TGF- β 1 overexpression enhanced progression of carcinogen-induced skin cancers toward the malignant

spindle cell phenotype in transgenic mice expressing high levels of TGF- β in the skin. The TGF- β -induced epithelial to mesenchymal transition in Ha-*ras*-transformed mammary epithelial cells involves disrupted cell-cell adhesion and the loss of epithelial cell polarity in addition to causing the cells to become more spindle shaped and invasive. The loss of cell polarity in response to TGF- β appears to be the result of a disruption of ZO-1 and F-actin proteins comprising the tight junctions in mammary epithelial cells.

There also is an important regulatory interaction between the TGF- β and cyclooxygenase-2 (COX-2) pathways. Forced overexpression of COX-2 in the nontransformed RIE-1 cells results in downregulation of the T β RII, and forced overexpression of COX-2 in a human colon cancer cell line results in increased secretion of TGF- β 1 from those cells. TGF- β synergistically enhances the expression of COX-2 in conditionally Ha-*ras*-transformed RIE-1 cells, and the increase in COX-2 expression by TGF- β in the context of *ras* transformation occurs primarily through a marked increase in the stability of the COX-2 mRNA.

The predominant effect of TGF- β appears to be dependent on the context of the responding cell. Thus, the divergent effects of TGF- β in carcinogenesis may depend on the proliferative capacity and state of differentiation of the epithelial cell, both of which may be altered during the process of neoplastic transformation. Clearly, TGF- β signaling has an important tumor suppressive role; however, after transformation has occurred, TGF- β effects may be detrimental and may actually promote tumor cell survival, invasion, and metastasis. Recent work suggests that these effects may involve TGF- β regulation of COX-2 and other pathways that may contribute to tumor cell aggressiveness.

TUMOR HOST INTERACTIONS

There are many complex pathways within the tumor cell that allow it to express a phenotype different from that of normal replicating cells. There are important interactions between the tumor cell and surrounding normal cells that enhance the attributes normally ascribed to cancer. In the Hanahan and Weinberg six capability model, the two capabilities most involved in these tumor interactions are sustained angiogenesis and tissue invasion and metastasis. Both of these processes involve a carefully coordinated interplay between a variety of cell types, each influencing the other's growth and development.

Tumor Angiogenesis

- 4 The observation that tumors require the establishment of a vasculature to grow larger than several millimeters is one that was clearly elucidated by Judah Folkman in 1971. Since that time there has been a growing realization that tumors must develop a network of vessels to grow, invade, and metastasize. A variety of signals allow tumor cells to stimulate vessel ingrowth. One of the more commonly studied cytokines is vascular endothelial growth factor (VEGF). Many studies have linked the ability of a tumor to produce VEGF with its malignant potential. This has been shown in breast cancer, colon cancer, and kidney cancer, as well as others. VEGF is actually a family of cytokines, which act on the endothelial cell through a variety of surface receptors. The most common VEGF isoforms (A, B, and C) act on predominantly three endothelial cell receptors (VEGF-R 1, 2, and 3). VEGF receptors 1 and 2 bind VEGF and act predominantly to modulate endothelial cell proliferation and maturation in blood vessels. VEGF-C, working through VEGF receptor 3, exerts its effects predominantly on the endothelial cells of the lymphoid system.

Several lines of evidence have demonstrated the importance of VEGF as a tumor-derived factor for stimulating and recruit-

ing a blood supply. Models have been developed that demonstrate the importance of VEGF in tumorigenesis. Using a transgenic mouse model of pancreatic islet carcinoma (RIP1-Tag2), Hanahan et al. demonstrated that five VEGF lineage genes are expressed in normal islets and throughout islet tumorigenesis. When this group produced an islet beta cell-specific knockout of VEGF-A, the resulting islets in these animals had reduced vascularity but retained their normal physiology. In RIP1-Tag2 mice in which most of the oncogene expressing cells had deleted the VEGF-A gene, both angiogenic switching and tumor growth were disrupted, as was the degree of neovessel formation. This elegant work demonstrates the crucial role of VEGF in angiogenesis. Although such experimental work is compelling, clinical data support this notion further.

A humanized mouse monoclonal antibody against VEGF (bevacizumab, Avastin, Genentec, Inc.) has recently completed phase III clinical trials and has received Food and Drug Administration (FDA) approval based on its activity in patients with colon cancer. In a prospective randomized phase III trial in renal cancer, James Yang et al. demonstrated that systemic administration of anti-VEGF antibody to patients with metastatic renal cell carcinoma resulted in a significant prolongation in the time to disease progression when compared with patients receiving a placebo. Herb Hurwitz et al. combined anti-VEGF antibody with a three-drug chemotherapy regimen consisting of 5-fluorouracil (5FU), leucovorin, and irinotecan for patients with metastatic colorectal carcinoma and compared this combination with the three-drug chemotherapy regimen alone. The addition of the anti-VEGF antibody to the standard chemotherapy regimen resulted in an improved response rate and an improved disease-free and overall survival. This clear relationship between blockade of factors known to induce tumor vasculature leading to antitumor effects seen clinically in patients underscores the importance of the angiogenic process in human tumors.

To gain a better understanding of the complex relationships between tumor cells and the surrounding stromal cells, including the endothelium, a basic understanding of the molecular processes involved in endothelial cell growth and differentiation is important. Indeed, regulation of vessel growth and proliferation is an important component of normal homeostatic mechanisms. Following embryogenesis and tissue formation, the growth of new blood vessels in normal tissues is carefully controlled and regulated. In addition to VEGF, there are a number of other regulatory cytokines, both initiators of vessel formation and inhibitors, that are regulated in a careful balance. An understanding of this balance may allow a more informed selection of targets for future cancer therapies. In addition to VEGF, other stimulatory cytokines have been shown to play an important role in a tumor's ability to recruit a vasculature. Among these, acidic fibroblast growth factor (aFGF) and basic fibroblast growth factor (bFGF) as well as placental-derived growth factors play important roles.

In addition to a careful balance of cytokines, integrin signaling plays an important role in regulating angiogenesis. When quiescent blood vessels are compared to activated or actively proliferating blood vessels, the panel of expressed integrins differs. Integrins such as $\alpha v \beta 3$, which plays an important role in endothelial cell adhesion to vitronectin (a component of the extracellular matrix), is differentially expressed in the vasculature of certain tumors when compared to other histologies and to normal tissues. Endothelial cells differ in their expression of various surface proteins depending on the tissue in which they reside. Work by investigators such as Pasqualini and Arap has demonstrated the diversity of endothelial cells and underscores the important observation that not all endothelial cells are the same.

In landmark studies using phage display techniques, Pasqualini and Arap have demonstrated that endothelial cells have unique surface markers that define their differences based on their tissue of origin. These so-called endothelial cell zip

codes may provide a unique target for delivering endothelial cell-directed therapies. This diversity may also explain, in part, the differences in response rates of various tumors to different angiogenesis inhibitors.

A series of elegant experiments performed by Kalluri et al. focused on the relationship of endothelial cell surface integrin expression to the response of those endothelial cells to the effects of various angiogenesis inhibitors. Kalluri showed that endothelial cells expressing $\alpha v \beta 3$ responded to the collagen IV derivative tumstatin and not to endostatin. Conversely, endothelial cells expressing the integrin $\alpha 5 \beta 1$ responded to endostatin rather than tumstatin. This was confirmed in animals bearing tumors. This specificity for certain integrin profiles is a critical observation in choosing the appropriate angiogenesis inhibitor and may explain, in part, the early clinical results with this class of agents.

A host of counterregulatory angiogenesis inhibitors have also been elucidated. These include thrombospondin 1, angiostatin, endostatin, and a series of collagen IV derivatives known as canstatin, arresten, and tumstatin. Table 13.3 lists some of these angiogenesis inhibitors; however, the field is rapidly growing and evolving and therefore any list must be considered representative rather than all-inclusive. The balance between proangiogenic factors and angiogenesis inhibitors was termed the “angiogenic switch” by Hanahan and Folkman. Tumors can activate this switch by changing the relative balance between inducers and inhibitors. How this balance is altered is the subject of ongoing study.

An intriguing possibility is that naturally occurring angiogenesis inhibitors play a gatekeeper function by inhibiting the progression of premalignant lesions by preventing their

ability to recruit a blood supply. Thrombospondin 1 (TSP-1) has been implicated as a putative regulator of such a process. Preclinical mouse models as well as studies of clinical samples have shown an inverse relationship between the level of TSP-1 expressed and the invasive potential of the tumor. This relationship has also been identified in cervical cancer specimens.

Both endostatin and tumstatin have also been implicated in such a gatekeeping role. A curious clinical observation is that patients suffering from Down syndrome have a distinctly lower incidence of the common solid tumors than the general population. As Down syndrome patients have lived longer, they have a much lower rate of lung, breast, and colon cancers. Down syndrome is caused by trisomy of chromosome 21, which is the location of the gene coding for collagen XVIII, the precursor of endostatin. Down syndrome patients have higher circulating levels of endostatin than the normal population, perhaps due to the extra copy of the collagen XVIII gene on the additional chromosome 21. Kalluri has postulated that these elevated levels of circulating endogenous angiogenesis inhibitors may function as endothelium-specific tumor suppressors. An attractive future strategy for tumor prevention might involve exogenous administration of these inhibitors or, alternatively, administration of small molecules that raise the circulating levels of endogenous inhibitors, thus decreasing the ability of noninvasive lesions from developing an invasive phenotype.

Tissue Invasion and Metastasis

Although the primary tumor can cause significant morbidity and even death, by far the majority of deaths due to cancer result from metastatic disease. Metastatic disease remains the most difficult component of cancer to treat, and therefore a thorough understanding of the processes that lead to the ability of cancer cells to spread to and grow in distant sites is critical. In the past, much work focused on the complex process of metastasis was observational; however, new tools now make it possible to study the pathways involved at a molecular level.

For tumor cells to invade into surrounding tissue and gain access to the lymphatics and blood vessels, a number of changes must take place. The normal cell surface proteins, which mediate contact inhibition and allow for normal anchoring to the extracellular matrix (ECM), must be perturbed. Two classes of such proteins are the cell-cell adhesion molecules (CAMs) and the integrins.

One example of an important CAM is E-cadherin, a member of the calcium-dependent cadherin family. E-cadherin is expressed on epithelial cells and helps to mediate antigrowth signals between cells. E-cadherin forms bridges between cells and transmits antigrowth signals via contact with β -catenin in the cytoplasm and downstream signaling via Lef/Tcf transcription factor. Mutations in E-cadherin or β -catenin can result in the loss of antigrowth signals and contact inhibition, leading to epithelial carcinomas.

A member of the immunoglobulin super family, N-CAM, is another example of a CAM that plays a pivotal role in preventing invasion and metastasis. Mutations in N-CAM can result in a change in isoform from an adhesive to a poorly adhesive phenotype. These mutations have been identified in small cell lung cancer and Wilms tumor.

Integrins play a critical role in anchoring cells to the ECM. Different cell types rely on different integrins to perform this function. Successful interaction between an integrin and the ECM can suppress growth signals. Integrins are often made up of an α and a β subunit. The switching between these subunits can result in differing phenotypes with respect to cell growth and invasion.

Beyond contact inhibition and anchorage dependence, cells must also shift in their ability to produce enzymes, which allow for the degradation of the basement membrane and ECM to allow invasion and migration. Differential expression of proteases can allow for tissue invasion and access to lymphatics and vessels, which can provide a conduit to distant organ sites.

Once a tumor cell loses contact inhibition and expresses proteases, there is no guarantee that it will be able to grow in a distant organ such as the lung or liver. In addition to surviving the trip to the distant site, it must be able to take up residence in the organ and grow. Not every tumor cell that successfully reaches a distant site will be able to multiply and grow successfully. Some organs do not readily allow for the growth of cells of certain histologies (e.g., colon cancer does not commonly metastasize to the kidney). In some very elegant experiments, Fidler has studied this “seed and soil” phenomenon.

Fidler et al. looked at the ability of orthotopically placed colon cancer cells implanted in the cecum of mice to effectively metastasize to other organs. When these cells were implanted in the cecum and normal mesenteric vascular anatomy drained the site through the mesenteric vein to the portal vein and into the liver, liver metastases were seen to develop in these animals. However, when Fidler rerouted the venous drainage from the colon by reimplanting the mesenteric vein into the renal vein, metastases did not develop in the kidney. Clearly, some growth factors were present in the target organ or cell surface interactions between the tumor cell and the cells of the target organ that allowed colon cancer to grow in the liver but not in the kidney. Such organ predilection for tumor metastases has also been observed clinically.

Ocular melanoma, melanoma that develops from the pigmented cells within the eye, can metastasize systemically. The most common site of metastases for ocular melanoma is the liver. In fact, the majority of patients with metastatic ocular melanoma present initially with isolated liver metastasis. There is no clear-cut anatomic drainage pattern from the eye to the liver. In fact, when liver metastases are successfully treated, ocular melanoma can grow in other sites, such as the lungs and subcutaneous tissues. However, the liver as a first site for the spread of ocular melanoma clearly indicates some “seed and soil” relationship that promotes the ability of these cells to grow in a specific site.

Other examples of specific sites for metastatic disease are more easily understood based on venous drainage. Colon cancers arising above the peritoneal reflection often metastasize to the liver consistent with the mesenteric venous drainage via the portal system. Rectal cancers below the peritoneal reflection, which are drained by the pudendal veins into the caval system, often metastasize first to the lungs.

Although much of the focus of understanding tumor invasion and metastasis has focused on the tumor cells themselves, there is increasing evidence that the host may play a facilitative role in the ability of cells to invade and metastasize. Kent Hunter and his group at the NCI have investigated the role of host genetics and tumor metastasis. Hunter's group observed that, although a typical tumor can shed millions of cells into the bloodstream daily, very few clinically relevant metastases are ultimately formed. Using transgenic mouse models, Hunter has demonstrated that tumor cells carrying mutations in key metastasis-associated genes may demonstrate the ability to metastasize in certain strains of mice while they are unable to metastasize in other strains despite their ability to form tumor nodules. Expression of genes that are important for the ability of tumor cells to metastasize has also been shown to be altered in the host tissues themselves. The hypothesis that particular genetic mutations or polymorphisms in the host may make one patient more prone to metastatic disease than another is an intriguing one that warrants further investigation. If such markers could be identified, then patients at higher risk for metastases could be treated with more aggressive adjuvant therapies following surgical resection.

By contrast, those patients without such a predisposition may do well with surgical resection of the primary lesion alone.

THE FUTURE OF CANCER THERAPY

Throughout the 20th century, the standard approaches for the treatment of cancer included surgical resection, radiation therapy, and chemotherapy. Although advances in specific technical applications and in combinations of therapies were made, these three broad modalities remained the foundation of therapeutic approaches. This section focuses on novel strategies for treating cancer that may serve to complement and in some cases replace the traditional paradigm of surgery, radiation, and chemotherapy.

Targeted Molecular Therapies

The explosion in information and the increase in our understanding of the basic pathways involved in the transformation of normal cells into invasive cancers have ushered in a new field of oncologic research. The concept behind molecular therapeutics is that a more thorough understanding of the alterations in specific pathways that result in the cancer phenotype may allow for the development of agents that either block a pre-cancer phenotype or replace factors that inhibit the transformation to cancer. It could be argued that many standard chemotherapies work in this manner. Alkylating agents as well as antimetabolites indeed target specific structures such as DNA, which are critical for tumor cells to divide and proliferate. However, these agents for the most part do not distinguish between normal cells and tumor cells. The promise of molecular therapy is the ability to make such a distinction. The importance of this is obvious. By distinguishing normal cells from neoplastic cells, toxicity may be reduced and efficacy increased.

One example of this strategy is the development, application, and subsequent FDA approval of the agent imatinib (Gleevec). Imatinib is an inhibitor of the Bcr-Abl kinase and was initially developed as a treatment for Bcr-Abl-positive leukemias. Imatinib was also found to inhibit other receptors, which signaled through kinases such as PDGF-receptor as well as c-Kit. This observation led to the application of imatinib to tumors beyond leukemias such as gastrointestinal stromal tumors (GISTs). The understanding of the importance of receptor signaling in the transformation of neoplastic cells allowed for the development of an agent that targeted these receptor kinases, thus blocking their activity.

Additional receptor kinase inhibitors have been developed against other receptors that have been shown to play an important role in cancer invasion and metastasis. EGF-R has been shown to play an important role in head and neck cancers, non-small cell lung cancers, and pancreatic cancers. Several agents have been developed that block the activity of this receptor. The small molecule tyrosine kinase inhibitor gefitinib (Iressa) has received FDA approval for the treatment of non-small cell lung carcinoma. Cetuximab (Erbix) has been used for head and neck cancers as well as colon cancer. Table 13.4 gives a representative list of a number of targets and the agents that have been developed to inhibit them. The VEGF receptors also signal through kinases and can be blocked by a variety of agents still in clinical trials. These agents have been utilized alone and in combination with more conventional cytotoxic chemotherapies.

The expression of HER2 (neu) in breast cancer has been shown to influence the aggressiveness of these tumors. For those patients with breast cancer that expresses HER2, the agent trastuzumab (Herceptin), a humanized monoclonal antibody, has been used with success to block HER2 signaling.

TABLE 13.4**MOLECULAR TARGETS AND THE AGENTS DEVELOPED TO MODULATE THEM**

TARGET	AGENT	MANUFACTURER
Bcr-abl	Gleevec	Novartis
HER2 (neu)	Herceptin	Genentech

Herceptin in combination with chemotherapy for patients with tumors expressing HER2 has been shown to be superior to chemotherapy alone.

These targeted agents represent an important new strategy, and the number of new agents in the study is likely to increase as new targets are identified. In many cases, the evaluation of these agents will require the development of novel monitoring techniques that can reveal if the targeted pathway is being effectively modulated. One example of this is the use of fluorodeoxyglucose (FDG) positron emission tomography (PET) scans and imatinib in the monitoring and treatment of patients with GISTs.

Another area of active investigation is the development of agents that modulate the methylation status of DNA. DNA methylation is an epigenetic event, which commonly occurs in the cell and allows for the control of gene expression. Methyl groups added to specific sequences (known as CpG islands) generally in the region of promoters result in the silencing of gene expression.

Hypermethylation often occurs in cancer. Most often, the genes that are susceptible to hypermethylation are those involved in cell cycle regulation, DNA repair, apoptosis, drug resistance, differentiation, angiogenesis, and metastasis. Hypermethylation can result in the inactivation of normally reactive tumor suppressors, which would otherwise prevent malignant transformation. Agents that result in DNA demethylation are undergoing active study as anticancer therapies. Agents such as decitabine reverse methylation in a number of tumor lines and have been shown to act on solid tumors as well in clinical trials. Other strategies involve targeting histone deacetylase (HDAC). HDAC is an important enzyme that is activated by DNA methylation to repress gene expression. HDAC inhibitors have been shown to increase gene expression from methylated genes.

Although the majority of cancers demonstrate hypermethylation, there are some that have evidence of hypomethylation, such as breast, cervical, and brain tumors. Hypomethylation is thought to activate tumorigenesis by turning on oncogenes such as *c-myc* and H-ras. Clearly, agents that result in demethylation will not be universally applicable to all cancers, and site-specific methylating agents may also be needed.

Another exciting field of investigation is in the ability to silence specific gene transcripts. If a tumor is known to overexpress K-ras, having the ability to turn off this expression would be advantageous. Small interfering RNA (siRNA) is a type of RNA designed to bind to messenger RNA, resulting in the degradation and removal of the message. RNA interference can be incorporated into a strategy to decrease the available message for subsequent translation. These siRNA can be generated as short oligonucleotide DNA fragments or delivered in a plasmid form for expression within a cell. In vitro and in vivo experiments have demonstrated the efficiency of this strategy of gene silencing and efforts are under way to develop methods for delivering siRNA in a clinical setting.

Gene Therapy

- 5 Despite the controversy surrounding human clinical trials using gene therapy, this strategy remains a promising approach for the treatment of patients with cancer. Gene therapy involves the delivery of a cDNA coding sequence for a particular gene of interest via a vector to a host organism with subsequent expression of that gene and production of the gene product. The gene product can provide a missing protein whose function in the case of cancer results in the suppression of the neoplastic phenotype or the protein can result in the lysis or destruction of the tumor or the tumor's associated vasculature. Many genes have been considered as likely candidates for gene delivery strategies to treat tumors. There are also several different vector systems that can be utilized to deliver these genes.

Vectors. The choice of a vector, which is a term used to describe the carrier for the gene sequence that is being delivered, depends to a certain degree on the route of administration, the target tissue, the amount of gene product one hopes to produce, and finally the duration of expression of the gene that is necessary to effect a response. Vectors tend to be categorized into two major classes. Nonviral vectors including plasmid DNA, liposomes, nanoparticles, and other synthetic carriers are attractive in that there is generally little to no immune response from the host and no endogenous viral proteins produced. In addition, these vector systems tend to be transient in their expression and, unless otherwise engineered, do not integrate into the host genome. The downside of nonviral vectors is that both the level of gene product expression and the duration of expression tend to be less than with viral vector systems. Viral vectors have the advantage of efficient transfection or transduction of host cells and sustained elevated levels of gene expression. The disadvantage is their potential immunogenicity, which may render multiple administrations less successful as well as increase the potential for host tissue toxicity.

Both nonviral and viral vector systems can be engineered to target specific tissue beds or tissue types and be delivered in a nontargeted way to host organs such as the liver. The choice between a targeted or nontargeted vector generally depends on the particular gene to be expressed and the ultimate goals of the therapy. This strategy has been illustrated by the application of antiangiogenic gene therapy to the treatment of cancer.

The goal of antiangiogenic gene therapy is to deliver an angiogenesis inhibitor in such a way that the body produces the protein of interest, thus eliminating the difficulties in recombinant production and the need for repeat administration of these proteins. Two strategies have been employed to deliver antiangiogenic agents via gene therapy (Fig. 13.11). The first is to engineer the vector system to target the gene of interest to the tumor cell or the tumor-associated vasculature. The advantage here is that relative tissue levels of the agent of interest can be significantly higher than those that are achieved through systemic production. In addition, genes that produce

FIGURE 13.11. Strategies for antiangiogenic gene therapy. **A:** Tumor-directed antiangiogenic gene therapy facilitates paracrine activity and avoids systemic toxicity. **B:** Systemic antiangiogenic gene therapy utilizes normal host tissue such as the liver as a “factory” to elevate systemic levels of the gene product. (Adapted from Feldman AL, Libutti SK. Progress in antiangiogenic gene therapy of cancer. *Cancer* 2000;89:1181.)

a product with direct cytotoxicity to the cancer cell or the tumor’s associated vasculature can be administered in a targeted way so as to reduce potential toxicity to normal tissues.

An alternative strategy is to deliver a vector to an organ such as the liver resulting in efficient transfection of hepatocytes with the gene for the angiogenesis inhibitor. The goal in this strategy is to harness the liver as a “factory” to produce circulating levels of the angiogenesis inhibitor to prevent the further growth and spread of micrometastatic disease throughout the body. Viral vectors such as adenovirus or adeno-associated virus with their native predilection for liver infection owing to CAR receptor uptake have been the vectors of choice for this approach. However, nonviral vectors such as liposomes tend to be taken up by the reticular endothelial system in the liver as well, and they also result in sustained gene expression and circulating levels of the protein. Table 13.5 lists various genes coding for angiogenesis inhibitors as well as the vectors used for their delivery that have been studied.

In addition to gene therapy strategies that employ the replacement of a gene such as p53 or the delivery of a cytotoxic gene such as thymidine kinase and ganciclovir therapy, the use of cytotoxic vectors alone has shown some promise. Vaccinia virus is a cytoplasmic virus that is related to the virus causing smallpox. Vaccinia virus delivery results in the infection and subsequent lysis of the cells infected. Studies utilizing vaccinia targeted to tumors have demonstrated the potential for this strategy in inhibiting the growth and spread of tumors.

Several clinical trials have been conducted utilizing gene therapy for cancer. Adenovirus carrying p53 has been studied in both direct arterial infusion into the liver as well as the treatment of glioma, lung cancer, ovarian cancer, and breast cancer. Recurrent head and neck cancer has also been studied. So-called suicide gene therapy utilizing the herpes simplex virus thymidine kinase gene and the prodrug ganciclovir has been studied in the clinic. Patients with mesothelioma have been studied in a phase I trial using this strategy, as have patients

with prostate adenocarcinoma using direct injection of an adenovirus expressing hsv-tk followed by ganciclovir exposure. These studies have demonstrated the safety of this strategy, although studies to evaluate efficacy are still under way.

The future of gene therapy for cancer is dependent on several important lines of investigation. Improved vectors are needed that minimize toxicity, allow for specific targeting, decrease the host’s immune response or prevent a host immune response, and can be produced efficiently for clinical use. The judicious selection of the appropriate genes to deliver in such a strategy is dependent on further investigation into the molecular pathways that are important to the malignant phenotype.

Immunotherapy

Harnessing the body’s immune system to attack cancer is an attractive strategy and area of investigation. Tumors express antigens that are often different from the antigens expressed by the normal cells. There are two main approaches for the use of immunotherapy to treat patients with cancer. The first involves the use of vaccine therapy to stimulate the body’s native immune system, mainly antigen-presenting cells and lymphocytes, to react specifically against the tumor antigens resulting in tumor regression. The second is the transfer of lymphocytes isolated from the patient’s tumor tissue (tumor infiltrating lymphocytes [TILs]) that have been selected for their immunoreactivity against the patient’s tumor.

Vaccine therapy may utilize peptides derived from the protein sequence of the cancer antigen, gene therapy with vectors carrying a coding sequence for the peptide or antigen, or, alternatively, the delivery of whole tumor lysate providing a variety of antigenic stimuli. Once vaccinated, the protein or peptide is processed by antigen-presenting cells in the context of the patient’s class I major histocompatibility complex (MHC) molecule, thus stimulating a lymphocyte response to the tumor.

TABLE 13.5**ANTIANGIOGENIC GENE THERAPY: GENES AND VECTORS**

■ GENE	■ DELIVERY VECTOR	■ FINDINGS
Angiostatin	Adeno-associated virus	Supernatant fluid from transduced tumor cells inhibited endothelial cell proliferation in vitro.
	Cationic liposome: DNA complex	Supernatant fluid from transfected tumor cells inhibited angiogenesis in the in vivo Matrigel model.
	In vitro transfection	Transfection of murine fibrosarcoma cells inhibited their growth as primary or metastatic tumors in mice.
	In vitro transfection Retrovirus	Transfection of murine B16F10 melanoma cells inhibited their growth as primary or metastatic tumors in mice. In vitro transduction of glioma cells inhibited their growth in mice.
	Adenovirus	Stereotactic injection into intracerebral gliomas inhibited tumor growth in mice.
	Adenovirus	Pretreatment with intravenous adenovirus inhibited establishment and growth of C6 rat gliomas in mice.
Endostatin	Cationic liposome:DNA complex	Intravenous injection of liposome:DNA complexes reduced B16F10 murine melanoma metastasis.
	Adeno-associated virus	Supernatant fluid from transduced tumor cells inhibited endothelial cell proliferation in vitro.
	In vitro transfection	Stable transfection of mouse and human tumor cell lines inhibited formation of lung and liver metastases in mice.
	Polymerized plasmid DNA	Intramuscular injection of endostatin plasmid inhibited syngeneic tumor growth and tumor metastases in mice.
	Cationic liposome:DNA complex	Intravenous injection of liposome:DNA complexes inhibited growth of human breast carcinoma in nude mice.
	Adenovirus	Intravenous injection of recombinant adenovirus inhibited growth of subcutaneous tumors in nude mice.
IL-4	Adenovirus	Intravenous injection of recombinant adenovirus inhibited subcutaneous tumor growth and prevented lung metastases in nude mice.
	Adenovirus	Intravenous injection of recombinant adenovirus inhibited subcutaneous tumor growth and prevented lung metastases in nude mice.
IL-4	Retroviral packaging cells	Stereotactic injection inhibited angiogenesis and growth of intracerebral rat gliomas and was immunostimulatory.
IL-10	In vitro transfection	Transfection of human melanoma cells inhibited angiogenesis, tumor growth, and establishment of metastases.
	In vitro transfection	Transfection of human prostate cancer cells inhibited their growth in nude mice
IL-12	Semliki Forest virus	Intratumoral injection inhibited B16 melanoma angiogenesis and growth in mice independent of immune response.
IFN- α TIMP-1	In vitro retroviral transduction	Transduction of human prostate carcinoma cells inhibited their ability to form tumors and lymph node metastases in nude mice.
	Adenovirus	Adenoviral infection of endothelial cells inhibited their migration in vitro.
TIMP-2	In vitro transfection	Transfection of B16F10 murine melanoma cells inhibited angiogenesis, tumor growth, and metastases in mice.
TSP-1	Liposome:DNA complex	Intravenous injection of DNA complexes encoding a TSP-1 fragment inhibited human breast carcinoma growth in mice.
p16	Adenovirus	Pretreatment with virus inhibited the ability of glioma cells to induce angiogenesis in a dorsal air sac model in nude mice.
p53	Liposome:DNA complex	Intravenous injection inhibited human breast carcinoma growth associated with decreased blood vessel density in nude mice.
	Liposome:DNA complex	Intravenous injection reduced angiogenesis and inhibited establishment of B16F10 lung metastases in C57BL/6 mice.
PF-4	Adenovirus	Coinjection of adenovirus with glioma cells under renal capsule of nude mice inhibited tumor growth and vascularity.
EMAP-II	Vaccinia	Intravenous injection of vaccinia enhanced tumor sensitivity to TNF associated with endothelial cell TNF receptor upregulation.

From Feldman AL, Libutti SK. Progress in antiangiogenic gene therapy of cancer. *Cancer* 2000;89:1181.

Cancer vaccines have been utilized in clinical trials studying a variety of human tumors. Patients with melanoma, breast cancer, colon cancer, head and neck cancer, and renal cancers have been studied. Although several studies have demonstrated successful immunization of patients to tumor antigens, to date, there have been no successful trials demonstrating significant cancer regression to vaccine therapy alone.

Cell transfer therapy has demonstrated antitumor activity in patients. To date, the most effective immunotherapy that has been utilized for patients with melanoma and renal cell cancer has been the infusion of interleukin-2 (IL-2). IL-2 is a lymphocyte-stimulating cytokine that has a variety of effects on T cells. Response rates to the systemic administration of IL-2 for patients with both melanoma and kidney cancer are 15% to 20%, with complete responses being approximately 9%. Complete responses are often durable with a majority of patients enjoying a long-term disease-free survival beyond 10 years. Therefore, any new immunotherapy strategy must improve on these IL-2 results.

TILs can be grown successfully from melanoma. These lymphocytes can then be tested for their reactivity against the melanoma using cell lysis assays. The advantage of cell transfer approaches is the ability to administer extremely large numbers of highly selective cells that have demonstrated avidity for the tumor antigens as well as the ability to affect tumor cell lyses. In studies at the NCI, Rosenberg et al. have demonstrated the ability to effect regression of metastatic melanoma refractory to standard treatment in patients receiving a non-myeloablative preparative chemotherapy regimen followed by the administration of selected TILs and IL-2. Response rates of 40% have been achieved with such an approach. A new strategy involving the introduction of specific and reactive T-cell receptors into peripheral blood mononuclear cells may obviate the need for harvesting tumor-infiltrating lymphocytes and open the possibility of using this strategy to treat solid tumors other than melanoma.

Clearly, there is a role for immunotherapy in the treatment of cancer. The future involves a better understanding of the complex interactions that lead to the immune response so as to better harness this knowledge for the development for more effective therapies. Such an understanding of the molecules that suppress or activate the immune response has led to the identification of lymphocyte surface molecules such as CTLA-4. CTLA-4 is an important regulator of T-lymphocyte proliferation and function. When active, CTLA-4 suppresses lymphocyte activation. Antibodies against CTLA-4 have been utilized in clinical trials demonstrating that inhibition of this suppression can result in an immune response against tumors.

ROLE OF THE SURGEON IN CANCER TREATMENT

Modern cancer therapy involves a multidisciplinary approach consisting of a variety of specialists with diverse talents. These individuals can be physicians, nurses, physical therapists, pain and palliative care specialists, dietitians, and clergy. The cancer patient often presents with a complex series of medical and nonmedical issues that require a coordinated approach for the optimal delivery of care. The surgeon's role in this coordinated effort is critical. For many patients, their first experience with the health care team is with a surgeon for the management of their primary tumor. This requires that the surgeon have a good understanding of the roles of the other members of the team and an ability to coordinate their interactions to provide the patient with the best possible outcome.

Typically, surgeons are associated with the management of early-stage disease and are usually called on only to manage the complications of stage IV disease, such as bowel obstruction or bleeding. This paradigm is changing as it has become

increasingly evident that aggressive surgical approaches may be of benefit to patients with advanced-stage tumors. Throughout this text are descriptions of the role of surgeons for the management of early-stage disease. Therefore, this section focuses on surgeons' impact in the management and care of cancer patients with metastatic tumors.

6 Surgical resection of metastatic disease has been practiced for decades. For certain tumor types, most notably, colorectal cancer and sarcoma, surgical resection of metastases in the lung or liver has been associated with improved survival. This approach relies on the fact that metastatic disease is well localized to one or two organs and that resection of those sites can be done safely and completely.

In 2008, it is estimated that there will be approximately 150,000 new cases of colorectal cancer. Of these patients, 20% to 40% will develop liver metastases as the sole or dominant site of their disease progression. Approximately 10% to 20% of patients with liver metastases will have disease that can be resected and patients may potentially benefit from the intervention. For patients with metastatic colorectal cancer confined to the liver, the options for therapy include resection for those with resectable disease with or without the addition of the adjuvant therapy, and systemic therapies for those with unresectable disease relying on combinations of irinotecan, 5FU, leucovorin, oxaliplatin, and, most recently, bevacizumab (Avastin). Bevacizumab is an antiangiogenic agent that blocks VEGF. It was recently approved by the FDA for the treatment of advanced colon cancer. Regional therapies involving hepatic artery infusion or isolated hepatic perfusion are also options for patients with unresectable disease, as are radiofrequency ablation and cryotherapy.

For patients with resectable metastatic colon cancer involving the liver (similar results exist for isolated disease involving the lung), resection of disease is followed by 5-year survival in a significant fraction. A variety of studies evaluating the outcome and operative mortality for patients undergoing complete resection of isolated colorectal cancer metastasis to the liver demonstrate 5-year survival ranging from 26% to 40%. There is at present no systemic chemotherapy regimen that significantly improves on the 10% 5-year survival observed in the earliest 5FU and leucovorin studies. Therefore, it is important to identify those patients with metastatic colorectal cancer isolated to the liver who would be candidates for surgical resection and therefore potentially a cure.

It is important to properly stratify patients to determine which ones will likely derive the greatest benefit from resection. In a 1999 study, Fong et al. at Memorial Sloan-Kettering Cancer Center reported on the results of an analysis of more than 1,000 patients treated by surgical resection for stage IV colon cancer isolated to the liver. They analyzed prognostic factors using univariate and multivariate statistics and determined the factors that predicted a positive outcome for their patients. Among the influential factors were disease-free interval between resection of the primary tumor and first sign of liver metastasis, number of tumors in the liver, carcinoembryonic antigen (CEA) value, size of the largest liver lesion, and the nodal status of the primary tumor. Depending on the number of these factors, a prediction of the 5-year survival and median overall survival in months could be determined (Table 13.6).

This type of information is critical in deciding which patients would most likely benefit from an aggressive surgical resection for their liver lesions. These outcomes are improved by the ability to accurately stage patients preoperatively with modalities such as high-resolution computed tomography (CT), magnetic resonance imaging (MRI), and PET using FDG. Intraoperative ultrasound is also critical to the careful intraoperative staging of these patients not only for the detection of additional liver lesions but also for the accurate determination of anatomic relationships to choose the appropriate resection to perform. Improved operative techniques such as segmental resections, use of stapling devices and coagulation

CEA, carcinoembryonic antigen; OS, overall survival; RR, relative risk. Adapted from Fong Y, Fortner J, Sun RL, et al. Clinical score for predicting recurrence after hepatic resection for metastatic colorectal cancer: analysis of 1,001 consecutive cases. *Ann Surg* 1999;230:309.

devices, minimization of blood loss by extrahepatic ligation of the hepatic vein prior to dissection, and intermittent inflow occlusion of the porta hepatis have led to a significant reduction in morbidity and mortality. However, despite these advances, many patients are not candidates for surgical resection. The surgeon can still play a role in the aggressive management of these patients.

Regional therapies for cancer have been the subject of study for more than 50 years. A variety of regional therapies are presently available to treat isolated hepatic metastases that might not otherwise be amenable to surgical resection due to the number of lesions, underlying liver disease, or other comorbid medical conditions. These techniques include cryoablation, radiofrequency ablation, intra-arterial hepatic infusion chemotherapy, chemoembolization of tumors, intralesional injection of chemotherapy or alcohol, and regional perfusion through operative or percutaneous techniques. Isolated operative hepatic perfusion and percutaneous hepatic perfusion are two promising strategies for the treatment of patients with isolated hepatic colorectal cancer metastasis.

Isolated hepatic perfusion (IHP) is a complex surgical procedure that was first reported in the early 1960s. It involves the complete isolation of the vascular inflow and outflow of the liver to deliver, via the hepatic arterial circulation, high doses of chemotherapy or cytokines to treat lesions within the liver but to spare the rest of the body from potential toxicity. The liver is ideally suited to such an approach because the majority of liver tumors (approaching 100%) derive their blood supply from the hepatic arterial vessels, whereas the normal liver receives 75% of its blood flow from the portal system. This

FIGURE 13.12. Schematic diagram of the perfusion and veno-veno bypass circuits used during an isolated hepatic perfusion. For the perfusion circuit, blood is collected from the hepatic veins via an isolated segment of retrohepatic vena cava that has been carefully prepared by ligating dividing venous tributaries and the adrenal vein. This blood is returned to a heat oxygenator and is perfused back into the liver via the common hepatic artery (through a catheter in the gastroduodenal artery). The perfusate consists of packed red blood cells and chemotherapy in a crystalloid solution. Intrahepatic blood and portal blood is shunted via an extracorporeal bypass circuit to the axillary vein to maintain venous return to the heart.

FIGURE 13.13. A view of the retrohepatic vena cava following dissection for an isolated hepatic perfusion.

allows the differential delivery of chemotherapy to the liver tumor by infusing the agent directly into the hepatic arterial circulation. The venous effluent from the hepatic veins is collected in an isolated segment of retrohepatic vena cava and this blood is recirculated back through a perfusion circuit that maintains a constant perfusion of oxygenated blood carrying chemotherapy and cytokines to the liver.

Extrahepatic circulation is maintained by shunting the infrahepatic caval blood as well as the portal circulation through a pump to the axillary vein to maintain systemic blood pressure (Fig. 13.12). Careful dissection of the liver with

special attention to the retrohepatic vena cava is required to divide collaterals and prevent systemic exposure to the perfusion agent (Fig. 13.13). The portal structures must also be completely dissected to isolate the portal vein and hepatic vessels for cannulation (Fig. 13.14). The advantages of such an approach are the complete separation of the regional and systemic circulation eliminating or significantly reducing systemic toxicity. Dose escalation of the chemotherapeutic agents is now limited only by the liver's tolerance to these agents as opposed to bone marrow or other systemic sites. The liver generally has a much greater reserve and ability to recover than the bone marrow. This technique also allows the utilization of hyperthermia via this closed circulatory system that can be heated and oxygenated by an extracorporeal heart lung machine.

A number of centers both in the United States and in Europe have explored this technique; the largest experience has been in the Surgery Branch of the NCI. Alexander et al. have reported results for 51 patients with unresectable colorectal cancer metastases treated with an IHP using the chemotherapy melphalan (with or without TNF) with or without follow-up hepatic arterial infusion (HAI) with FUDR/LV. Results included a response rate of approximately 75% with a median survival of 16 months for those patients not receiving follow-up HAI therapy and 27 months for those receiving HAI therapy following their IHP. These results demonstrate that significant responses and an acceptable duration of response can be achieved for an aggressive surgical approach for patients with significant liver disease (Fig. 13.15).

The application of IHP to unresectable liver metastases demonstrates the potential role for the surgeon in the management of patients with metastatic cancer. Clearly, however, such an intervention requires significant resources and skill, which may not be available at every major medical center. Therefore, a need to adapt this strategy to a therapy that can be more safely and easily administered and that allows repeated administrations (IHP can only be performed once) would be desirable. Investigators are therefore evaluating whether or not a percutaneous approach to hepatic isolation can be utilized.

This technique relies on the use of balloons placed via a catheter percutaneously introduced into the vena cava through the femoral vein. The balloons can occlude above the hepatic veins and above the renal veins to isolate a segment of the vena cava. The catheter isolates hepatic venous effluent to allow for extracorporeal filtration of chemotherapy delivered to the liver through a separate catheter introduced into the hepatic artery

FIGURE 13.14. Complete portal dissection for isolated hepatic perfusion.

FIGURE 13.15. Magnetic resonance imaging of the liver for a patient with colorectal cancer metastatic to the liver before (*top*) and after (*bottom*) an isolated hepatic perfusion (IHP).

(Fig. 13.16). The filtered blood is then returned via the internal jugular vein to maintain venous return. A phase I trial was recently completed at the NCI demonstrating a safe dose of melphalan that can be delivered in this fashion. A multicenter phase III trial is now under way to evaluate the utility of this approach for metastatic melanoma (cutaneous and ocular) to the liver compared to best standard therapy.

Regional therapy can be applied to other locations in the body such as the limb (isolated limb perfusion for melanoma or sarcoma) and the peritoneal cavity. Peritoneal carcinomatosis secondary to a number of histologies including colorectal

cancer, gastric cancer, pancreatic cancer, and malignant mesothelioma can be addressed. Traditionally, surgeons have played a role in managing the complications of this entity such as ascites and obstruction. However, techniques such as surgical debulking and intraperitoneal chemotherapy are gaining prominence as a viable management strategy for treating patients with peritoneal carcinomatosis. Surgeons have a unique role to play and can make a significant impact in treating this condition.

Malignant peritoneal mesothelioma can result in significant abdominal pain and distention accompanied by anorexia and

FIGURE 13.16. Schematic diagram (A) and fluoroscopic image (B) depicting the technique of percutaneous hepatic perfusion.

FIGURE 13.17. Diagram of the setup for continuous hyperthermic peritoneal perfusion.

weight loss, ascites, and bowel obstruction. These complications can lead to death and there are no effective systemic treatment options. Although agents such as cisplatin and carboplatin as well as paclitaxel (Taxol) and doxorubicin (Adriamycin) have been used to treat this condition, response rates are low (<20%) and survival is poor. The technique of contin-

uous hyperthermic peritoneal perfusion (CHPP) involves an exploratory laparotomy with lysis of adhesions, tumor resection, omentectomy, and peritonectomy of involved peritoneal surfaces (Fig. 13.17). Organs such as the spleen, if significantly involved with tumor, are also resected. At the completion of resection, the abdomen is closed after the insertion of inflow and outflow catheters and temperature probes. Carcinomatosis can involve the surfaces of the mesentery, which can be very difficult to resect (Fig. 13.18). Best efforts are made to strip the peritoneal surface over the mesentery and to fulgurate small lesions with ball electrocautery.

These catheters are connected to a perfusion circuit with a roller pump and heat exchange coil to circulate hyperthermic intraperitoneal chemotherapy agents. At the completion of the perfusion the abdomen is irrigated, and a peritoneal dialysis catheter can be inserted for postoperative dwell therapy with additional regional chemotherapy.

In a study of CHPP for intraperitoneal mesothelioma, Park et al. summarized the results of 18 patients with peritoneal mesothelioma treated with CHPP from 1993 through 1998. Of these 18 patients, 13 had clinically significant ascites. Patients were treated with operative debulking and CHPP with cisplatin. After a median follow-up of 19 months, there were no operative or treatment-related mortalities, and the overall operative morbidity was 24%. Morbidity included wound infection, atrial fibrillation, pancreatitis, ileus, and line sepsis.

Nine of 13 patients with ascites had complete resolution of their ascites following a single procedure. Three other patients had resolution of their ascites after a second CHPP. The median progression-free survival was 26 months, and the overall 2-year survival was 80%. Although this study did not prospectively compare CHPP to systemic cisplatin, trials of intravenous cisplatin report survival data that are similar to untreated patients. The results of CHPP can be dramatic for patients suffering with the very morbid condition of abdominal ascites (Fig. 13.19).

Thus, the surgeon can play an important role in the management of not only patients with primary tumors but also patients with stage IV disease. Surgeons must familiarize themselves with the other available nonoperative options for their patients with cancer so the correct therapy can be selected for the appropriate patient. Further study is needed to identify therapies that will benefit patients with advanced disease.

CANCER DETECTION AND BIOMARKERS

Methods to enable more accurate early detection of cancer are an active area of investigation. Some of these methods are amenable to cancer screening, allowing assessment of large populations of at-risk patients to detect disease at its earliest possible time. Other methods are best applied to patients who have already been treated for their cancer and are being followed for signs of recurrence. This section highlights three areas that illustrate the possibilities for early cancer detection.

Imaging

Standard imaging techniques such as CT, MRI, and ultrasound have been applied to patients as a means of both screening and follow-up. Standard plain radiographs have also been used in this setting. As CT scans and MRIs have become more advanced with higher resolution and shorter scanning times, the sensitivity for lesion detection has been dramatically improved. One example has been the development of both CT and magnetic resonance (MR) colonography.

Colonography has been proposed as a means to screen patients for colon polyps and tumors in an effort to avoid the need for an optical endoscopic colonoscopy. Virtual colonoscopy using CT scanning was evaluated as a screening procedure for colorectal neoplasia in asymptomatic adults at the National Naval Medical Center in Bethesda, Maryland. A total of 1,233 asymptomatic adults (mean age 58 years) underwent a same-day CT colonography as well as an optical colonoscopy. The radiologist used a three-dimensional endoluminal display for the detection of polyps on the virtual colonoscopy. The physicians performing the optical colonoscopy did not know the results of the virtual colonoscopy for the initial examination. The sensitivity and specificity of virtual colonoscopy compared to optical colonoscopy were then compared to the findings of a final unblinded optical colonoscopy, which was used as the reference standard.

Sensitivity of the virtual colonoscopy for adenomatous polyps was 94% for polyps greater than 8 mm in diameter and

89% for polyps that measured at least 6 mm in diameter. The sensitivity of optical colonoscopy for adenomatous polyps was 88% to 92% for polyps greater than 8 mm in diameter and 92% for polyps measuring at least 6 mm in diameter. Of the patients screened, two polyps were found to be malignant and both of them were detected by virtual colonoscopy. With sensitivities and specificities that are approaching or better than those of optical colonoscopy, virtual colonoscopy using CT may become a screening procedure of choice. When lesions are detected, a follow-up optical colonoscopy can be performed to biopsy the lesion.

Noninvasive imaging can also be utilized in patients following the treatment of a cancer to detect early recurrence. In a study at the NCI, standard imaging techniques such as CT, MRI, and ultrasound were compared to PET using FDG, anti-CEA antibody immunoscintigraphy, and a blind second-look laparotomy for patients with a rising serum CEA following definitive management of colorectal cancer. In this study FDG-PET and blind second-look laparotomy were found to be the most sensitive methods for detection of recurrent disease. As a noninvasive screening method, FDG-PET was both sensitive and specific for the detection of recurrent disease in patients with a rising serum CEA and therefore is now recommended as an appropriate screening modality prior to any planned surgical management (Fig. 13.20). FDG-PET is also useful in the metastatic workup of patients with malignant melanoma, primary lung carcinoma, and esophageal cancers.

Dynamic enhanced MRI (DEMRI) has become a useful noninvasive imaging modality for the evaluation of the functional status of a tumor. Tumor blood flow and blood volume can be calculated from DEMRI images and thus, this noninvasive imaging method can be used to follow the response of a tumor to a variety of therapies. DEMRI has been successfully utilized for imaging primary breast cancers as well as for imaging metastatic sites from a variety of histologies. Images obtained from DEMRI can be utilized to determine residual areas of tumor activity following therapies to more accurately guide biopsies and further regional treatment.

The new frontier for cancer imaging is so-called molecular imaging. Although this term can encompass a variety of imaging approaches and methods, it is most commonly used to categorize techniques that rely on imaging a tissue based

FIGURE 13.20. Fluorodeoxyglucose positron emission tomography scan demonstrates a recurrent colon cancer in the bed of a previous right hemicolectomy that was not detected on computed tomography scan in a patient with a rising serum carcinoembryonic antigen.

on specific expression of receptors or pathways. In combination with molecular therapies, such imaging methods may allow for noninvasive monitoring of the activity of targeted agents.

A number of preclinical models have been developed to test molecular imaging strategies. Weissleder et al. have designed a number of noninvasive methods for imaging the activity of enzymes and pathways to predict the efficacy of molecular agents. One example is their use of iron oxide nanoparticles cross-linked to Cy-3 and Cy-5 fluorescent dyes. Using cathepsin-B cleavable linking peptides, activity can be measured via cleavage and determination of the ratio of the various fluorophores. By using fluorophores as well as iron particles, both fluorescent imaging and MRI of the tissue in question can be performed.

Specific tissue receptors can also be imaged noninvasively. Tumor vasculature is known to have an increased expression of integrins such as $\alpha v\beta 3$. Using RGD cyclic pentapeptides labeled with PET positron emitters, tissues with enhanced $\alpha v\beta 3$ expression can be imaged. Such techniques can be used to locate areas of increased tumor neovascular density and can also be utilized to follow the targeting or activity of $\alpha v\beta 3$ -specific agents.

Gene Expression Profiling

With the completion of the sequencing of the human genome, a wealth of information is now available regarding the roughly 30,000 genes that code for various proteins involved in normal cellular homeostasis. The dysregulation of these genes that occurs in neoplastic tissue can now be studied using microarray-based technologies.

Microarrays for the study of gene expression can utilize a variety of platforms, the most common of which are cDNA and oligonucleotide sequences. Nucleic acid sequences can be spotted on glass slides or on proprietary chips, allowing 20,000 or more coding sequences to be placed on a single slide (chip). These techniques allow high-throughput screening of

these genes from a variety of sources capable of yielding substrate RNA. Using linear RNA amplification techniques, even the smallest samples of RNA from fine-needle aspirates (FNAs) or microdissected tissues can be utilized for profiling. Gene expression profiling can be used to answer a variety of questions including the differences in gene expression pathways between malignant and normal tissues. Expression profiles can also be determined in tissues prior to and following therapies to better understand mechanism of action of a treatment. Recently, genomics approaches have been validated for the stratification of women with breast cancer for treatment with adjuvant therapy. Such approaches are useful in determining which patients may benefit from adjuvant chemotherapy or hormonal therapy and which patients will not, thereby avoiding unnecessary toxicity in patients unlikely to benefit from the therapy.

Complex bioinformatics software programs have been developed to allow a more thorough analysis of the data sets obtained through these studies. The National Institutes of Health (NIH) Center for Information Technology and the NCI have posted a series of bioinformatics tools to allow investigators to better study and understand the results of their microarray experiments. This Web site can be found at <http://nciarray.nci.nih.gov/>.

One example of the utility of microarray approaches for the diagnosis of cancer is the differentiation of benign versus malignant thyroid lesions. Approximately 10 million new thyroid lesions are diagnosed each year in the United States. Only 5% of these lesions are malignant. Although fine-needle aspiration has been utilized in an attempt to identify those patients with a thyroid cancer who require further management, straightforward cytologic examination of FNA samples often leads to indeterminate or nondiagnostic studies. A molecular method for distinguishing benign from malignant thyroid lesions would be helpful in identifying those patients who would most benefit from a surgical intervention.

Utilizing cDNA microarray, our group compared expression profiles of thyroid cancers (papillary thyroid cancers and follicular variant papillary thyroid cancers) to benign thyroid

lesions. Cluster analysis developed a model to predict the malignant potential of the tissue. Using this strategy, we identified 10 genes capable of differentiating a benign lesion from a malignant lesion. By using this technique, the diagnosis of thyroid cancer from FNA may be improved.

Microarray approaches have also been used to grade lymphoma as well as predict potential response to therapies. Childhood sarcomas have also been subclassified using a similar molecular approach. As these technologies improve, more widespread use of these molecular-based diagnostics will be feasible.

Proteomics

Genes mainly code for proteins that perform the various structural and functional roles in the cell. Proteins undergo a series of modifications to perform these jobs, most importantly glycosylation and phosphorylation. Although cDNA and oligonucleotide microarrays can determine levels of gene expression, they cannot elucidate the modifications that take place at the protein level.

Proteomics, or the direct study of proteins, allows for not only a quantification of the levels of proteins present in tissues but also a determination of the phosphorylation status of these proteins. Serum proteomics is an exciting new technology, which holds promise for the diagnosis of cancer from a sample of blood. Such an approach is now being applied to clinical samples.

Based on the assumption that patients harboring a malignancy have circulating proteins in their serum that are not present in unaffected patients, serum proteomics endeavors to distinguish a “biosignature” profile of human cancer. By taking samples from a population of patients with cancer and comparing the proteomic profile of their serum to that of a population of people without cancer, a pattern can be elucidated that identifies the at-risk population. The novelty of this approach is that, unlike investigating single specific biomarkers such as CEA for colon cancer or CA 19–9 for pancreas cancer, a serum proteomic approach requires no hypotheses about which proteins will be important to identify. In fact, thousands of proteins can be queried and utilized to form the biosignature. The most informative of these can be determined using various bioinformatics strategies to reduce the number to a manageable assay.

Applying this approach to patients with ovarian cancer, high-resolution spectral data have been obtained that demonstrated a specific pattern capable of distinguishing patients with stage I ovarian cancer from patients with more advanced ovarian cancer, as well as from normal healthy controls. As these techniques improve, they will no doubt be applied to other tumor histologies and will add to the armamentarium of diagnostic tests available to the clinician.

CLINICAL TRIALS

As knowledge increases regarding the pathways involved in tumorigenesis, novel agents will be identified that show promise in treating cancer. Although much can be learned about these agents in preclinical models, the ultimate evaluation of a new cancer therapeutic requires carefully conducted clinical trials.

Clinical trials involve the participation of patient volunteers. These volunteers agree to participate in studies that pose specific scientific questions to find improved strategies to prevent, diagnose, screen for, or treat a particular disease process. There are a number of types of clinical trials.

Prevention trials are designed to evaluate strategies or therapies aimed at preventing the development of cancer. These studies are most often conducted with healthy patient

volunteers who have not yet developed cancer but may or may not have a predisposition to develop cancer. Screening trials are aimed at finding improved ways to determine which patients or populations of patients are most at risk for developing cancer and therefore detect cancers in these patients at the earliest time point to be more effective in treating their disease.

Diagnostic trials are geared toward the study of procedures or tests that can identify cancer at its earliest possible stage. The testing of new diagnostics is often performed on patients who are already known to have cancer based on standard diagnostic tests. Supportive care (quality of life) trials are designed to investigate ways to improve the quality of life of patients in whom further therapies may not be available. These trials are of critical importance as they can often determine where new therapies may have a dramatic improvement in the symptoms of cancer and therefore decrease the suffering due to cancer in those patients.

Genetic studies can be standalone trials or a part of another trial. These studies may rely on the analyses of germline mutations in patients (e.g., studies of patients with familial cancer syndromes) or may rely on studies of somatic mutations in the tumor tissues themselves to understand pathways involved in tumor growth invasion and metastasis. Special considerations must be made when performing genetic studies that involve germline analysis as the findings of such studies may have far-reaching implications for the patient. Appropriate genetic counseling must be a part of the informed consent process for these studies.

The most common and familiar types of clinical trial are treatment trials, which are designed to evaluate new cancer therapies. Treatment trials are divided into different phases of evaluation for new anticancer agents. Phase I trials are performed to evaluate the safety and toxicity profile of a compound and are generally conducted in a dose escalation format. Patients receive progressively higher doses of the agent to determine the maximum tolerated dose and any dose-related toxicities. This allows for determination of the safe dose for evaluation in the next phase. Pharmacokinetics and pharmacodynamics can also be studied. These studies generally enroll 20 to 30 patients in cohorts of three patients per study dose level.

Phase II trials are focused on determining the efficacy of a given agent at its maximum tolerated dose (MTD). These trials generally focus on a given histology (or small number of histologies) to define the response rate and duration of response for the test compound. Responses are generally scored by measuring changes in the size of measurable lesions, typically using imaging studies or physical measurements of accessible tumors. Responses can also utilize changes in circulating biomarkers or other functional measures of tumor activity.

Most current treatment trials rely on the response evaluation criteria in solid tumors (RECIST) criteria for determining the activity of the test agent. When objective tumor response is the primary endpoint of the trial, only patients with measurable disease at baseline are generally included. Measurable disease is defined as the presence of at least one measurable lesion. Measurable lesions must allow for the accurate measurement in at least one dimension with the longest diameter greater than 20 mm using conventional techniques or 10 mm or larger utilizing spiral CT scan.

Nonmeasurable lesions are defined as all other lesions including smaller lesions, bone lesions, leptomeningeal disease, ascites, effusions, and so forth. Lesions can be measured utilizing best available methods such as CT and MRI or, in the case of accessible lesions such as cutaneous lesions, by direct caliper measurements. The RECIST criteria do not allow for the measurement of tumor markers alone to assess response.

The RECIST criteria call for the documentation of both target and nontarget lesions. The target lesions are defined as all measurable lesions up to a maximum of five lesions per organ

TABLE 13.7**BEST OVERALL RESPONSE CALCULATIONS BASED ON RECIST CRITERIA**

TARGET LESIONS	NONTARGET LESIONS	NEW LESIONS	OVERALL RESPONSE
CR	CR	No	CR
CR	Incomplete response/SD	No	PR
PR	Non-PD	No	PR
SD	Non-PD	No	SD
PD	Any	Yes or no	PD
Any	PD	Yes or no	PD
Any	Any	Yes	PD

CR, complete response; PD, progressive disease; PR, partial response; RECIST, response evaluation criteria in solid tumors; SD, stable disease.

and 10 organs in total that are representative of all involved organs. These should be measured at baseline. The criteria define, for the purpose of measurements, the total size of target lesions. This is defined as a sum of the longest diameter (LD) for all target lesions, which is calculated and reported as the baseline sum LD. This baseline sum LD is what is used as the point of reference to characterize all subsequent measurements and therefore objective responses. All other lesions that are not designated target lesions are defined as nontarget lesions and are scored only based on presence or absence rather than directed measurements.

Based on changes from the sum LD, the following response criteria are defined. For the evaluation of target lesions, a complete response (CR) is defined as the disappearance of all target lesions. A partial response (PR) is defined as at least a 30% decrease in the sum of the LD of target lesions when compared to the reference baseline sum LD. Progressive disease (PD) is defined as at least a 20% increase in the sum of the LD of target lesions or the appearance of one or more new lesions. Stable disease (SD) is defined as neither a sufficient shrinkage to qualify for PR nor a sufficient increase to qualify for PD.

With respect to the evaluation of nontarget lesions, a CR is defined as the disappearance of all target lesions and normalization of a tumor marker if measured. An incomplete response or stable disease is defined as persistence of one or more nontarget lesions and/or maintenance of tumor marker levels above the normal limits. Progressive disease is defined as one or more new lesions or the unequivocal progression of existing nontarget lesions.

The evaluation of response is generally recorded as the best overall response. Table 13.7 defines how best overall response is calculated based on both target and nontarget lesions. Once an overall response is calculated, the duration of this response is measured from the time that measurement criteria are met for CR or PR until the first date that recurrence or PD is objectively documented.

Strict approaches to the definition of response are critically important in evaluating the efficacy of agents in phase II trials. Notions such as “marginal response,” although potentially descriptive, are not rigorously supported and therefore not interpretable with respect to the activity of an agent. Adherence to the strict definitions allows for a more critical evaluation and therefore more useful decision making with respect to the development of a new cancer therapy. Once a response rate and duration of response are determined for an agent, a decision is made on whether or not to take that agent to further clinical evaluations.

Phase III clinical trials are conducted once the maximum tolerated dose of an agent has been tested in the phase II trial in a variety of histologies and has demonstrated reasonable response and duration of response data. Although phase I and phase II trials can often be conducted with fewer than 30 patients, phase III trials generally require hundreds or thousands of patients to have the appropriate statistical power and a sufficient variety of patient types to demonstrate definitive activity.

Phase III trials are typically designed to compare the test agent to standard therapy. The strongest design is a prospective randomized trial, in some cases blinding of the investigators and/or the patient to the receipt of the experimental therapy. Although phase III trials are the definitive studies to demonstrate the superiority of a new therapy over the previous standard, the majority of new cancer agents approved by the FDA are approved after successful phase II studies.

Recently, the concept of phase 0 trials has been introduced. These studies are usually conducted either prior to a phase I or between a phase I and phase II study. The purpose of a phase 0 trial is to evaluate the effects of an agent using novel biomarkers or other surrogates in a small number of patients at a dose that is predicted to be nontoxic. Such trials are especially useful in the evaluation of novel biologic or targeted therapies.

In addition to understanding the basic mechanics and nomenclature for clinical trials, research with human subjects must be conducted according to strict scientific and ethical principles. All federally supported clinical trials and trials evaluating new drugs or devices that are subject to FDA regulation are required to be reviewed and approved by an institutional review board (IRB). Most institutions require that all clinical trials and all human subjects research, regardless of funding, be reviewed and approved by their IRB.

The IRB is typically made up of physicians, nonphysician health professionals, laypersons, and statisticians who have the capacity to critically evaluate research studies or protocols to determine relative risk benefit for the patient volunteers. The IRB has the power to stop or hold clinical trials secondary to questions regarding patient safety. It is important that the IRB consider, in its evaluation of the risks and benefits of a particular protocol, the scientific design and questions being asked to determine if they are likely to be answered with the patient population under study. It is also important for the IRB to determine whether any conflicts of interest may exist with regard to the investigator conducting the trial and the agents being tested. If such conflicts exist, they should be clearly delineated in the protocol and consent document so that

potential patient volunteers are given a complete disclosure of any potential conflicting motivations for the investigators conducting the study.

As newer agents are identified and new classes of agents defined (biologic agents, molecularly targeted agents, antiangiogenic agents, etc.), modifications and adaptations of the traditional clinical trial phases may be implemented. As agents are identified that impact on a particular pathway, methods for measuring the activity of that pathway may need to be incorporated into the response criteria. Classic stopping rules for traditional chemotherapeutic agents, such as evidence of progressive disease, may need to be adjusted for agents that have a slow onset of activity and require prolonged administration to have an antitumor effect. Issues such as these are under constant evaluation by the FDA and the NIH, and updated information is constantly evaluated. For up-to-date changes in clinical trial strategies as well as access to searches for available clinical trials, the Web site <http://www.cancer.gov> is a useful online reference.

CHAPTER 14 ■ POLICY APPROACHES TO IMPROVING SURGICAL QUALITY

JOHN D. BIRKMEYER AND JUSTIN B. DIMICK

KEY POINTS

- 1 Commonly used quality indicators, including both volume- and risk-adjusted outcomes, readily identify groups of hospitals and surgeons with superior outcomes. They are not reliable in profiling performance for individual providers, however.
- 2 In surgery, the most familiar process compliance strategy is the pay-for-performance program of the Surgical Care Improvement Project, which aims to increase adoption of evidence-based practices related to perioperative care.
- 3 Current process measures do not reliably identify hospitals or surgeons with better outcomes. Higher leverage measures, including those that reflect important aspects of surgical decision making or operative performance, are needed.
- 4 Although prophylactic strategies aimed at avoiding complications in the first place are obviously important, “rescuing” patients once a complication has occurred may be even more critical in reducing current variations in hospital mortality rates.
- 5 Outcomes measurement and feedback may provide early benefits by capitalizing on the surgical “Hawthorne effect,” but they do not inform hospitals or surgeons about how best to improve.
- 6 The optimal strategy for improving surgical quality may depend on political realities, the clinical context, and which outcomes stakeholders hope to improve.

Improving the quality of surgical care is a public health imperative. Based on our extrapolations from national Medicare data, approximately 50,000 patients die every year undergoing surgery in the United States; perhaps 10 times that number experience serious complications. A growing body of literature suggests that a large proportion of surgical morbidity and mortality may be avoidable. Almost 10 years ago, the Institute of Medicine estimated that between 44,000 and 98,000 Americans die every year as a result of medical errors, at least half of whom are surgical patients.^{1,2} Evidence that morbidity and mortality vary widely across hospitals and surgeons further suggests opportunities for improvement. In addition to variation among individual providers,^{3–5} surgical outcomes differ according to a number of provider attributes, including procedure volume, surgeon subspecialty training, and other factors.^{6–8}

In response, payers, policy makers, and professional organizations have implemented a variety of different strategies aimed at improving surgical quality.⁹ Some of these efforts, including payers’ Centers of Excellence programs, aim to direct surgical patients to hospitals or surgeons with the best results (selective referral). Others, instead, strive to “raise the tide,” focusing on improving outcomes at all hospitals, particularly those with subpar results. Among broad-based quality improvement efforts currently under way, pay-for-performance programs are incentivizing hospital and surgeon compliance with specific process measures, most related to perioperative care (process compliance model). For example, the Surgical Care Improvement Project aims to improve practices related to prophylaxis against surgical site infection, venous thromboembolism, and ventilator-acquired pneumonia. In contrast, professional organizations, including the American College of Surgeons (ACS) and its National Surgical Quality Improvement Program (NSQIP), are focusing on outcomes measurement and feedback to hospitals (outcomes measurement model).^{10,11} These efforts are less prescriptive with regard to clinical practice and instead assume that hospitals and surgeons can figure out themselves how best to improve at the local level.

Although some might use different labels, selective referral, process compliance, and outcomes measurement represent the three dominant strategies for surgical quality improvement currently being employed in the United States. In this chapter, we review the relative strengths and weaknesses of each approach (Table 14.1). We also consider the optimal strategy for different clinical contexts and procedures, and how each strategy could be improved in the future.

SELECTIVE REFERRAL

With this approach, payers (usually) identify hospitals with the best results with selected procedures and direct care to these facilities. To achieve this end, they can employ selective contracting or tiered health plans and benefits packages that give patients financial incentives (lower copays or monthly premiums) to select higher-quality providers. Although also intended to enhance accountability and motivate quality improvement at the local level, public reporting of hospital performance is another obvious tool for effecting selective referral.

Among current examples of selective referral, the Leapfrog Group, a large coalition of public and private employers and purchasers, is promoting “evidence-based hospital referral” for selected procedures (coronary artery bypass graft surgery, aortic valve replacement, abdominal aortic aneurysm repair, bariatric surgery, esophagectomy, and pancreatic resection) based on both procedure volume criteria and hospital mortality rates.¹² Cardiac surgery, bariatric surgery, and breast cancer care are becoming increasingly popular targets for payers’ Centers of Excellence programs.

Such strategies reflect the natural response of payers (and many patients) to data indicating variation in provider performance with surgery. Among their advantages, selective referral can often be implemented expediently and inexpensively, particularly when based on simple structural measures of quality (e.g., procedure volume). For many procedures, commonly used quality indicators can reliably identify groups of hospitals and

TABLE 14.1**CHARACTERISTICS OF THREE DIFFERENT MODELS FOR REDUCING VARIATION AND IMPROVING SURGICAL MORTALITY**

	■ SELECTIVE REFERRAL	■ PROCESS COMPLIANCE	■ OUTCOMES MEASUREMENT
Goal/mechanism	Steer patients to best hospitals or surgeons	Improve care in all settings by increasing hospital compliance with evidence-based processes of perioperative care	Improve care in all settings by providing feedback on surgical outcomes; hospitals and surgeons implement improvement efforts at the local level
Examples	Leapfrog Group evidence-based hospital referral program Payers' Centers of Excellence programs in cardiac and bariatric surgery	Surgical Care Improvement Project (SCIP), other pay-for-performance programs focusing on practices related to reducing surgical site infection (SSI) and venous thromboembolism	Society of Thoracic Surgery database for cardiothoracic surgery American College of Surgeons' National Surgical Quality Improvement Program
Advantages	Inexpensive, expedient Traction with patients and payers	Likely to achieve rapid improvements in aspects of perioperative care	Measurement alone may be effective in improving outcomes ("Hawthorne effect")
Disadvantages	Highly polarizing (for providers) Hard to identify best providers (at individual level)	Improving processes related to secondary outcomes (e.g., SSI) may not reduce variation in mortality	Lack of insights about how best to improve; may limit ultimate extent of improvement Expensive

surgeons with superior outcomes. For example, data readily obtained from administrative data, including procedure volume and hospital mortality, not only describe past performance, but also forecast future performance with many procedures.¹³

Unfortunately, such measures are considerably less useful in discriminating performance among individuals, in part because provider-specific outcomes are statistically unstable. For example, Krumholz et al. used clinical data from the Cooperative Cardiovascular Project to assess the usefulness of the HealthGrades hospital ratings for acute myocardial infarction (based primarily on risk-adjusted mortality rates from Medicare data).¹⁴ Relative to one-star (worst) hospitals, five-star (best) hospitals had significantly lower mortality (16% vs. 22%, $p < 0.001$) after risk adjustment with clinical data. However, the HealthGrades ratings poorly discriminated among any two individual hospitals. In only 3% of head-to-head comparisons did five-star hospitals have statistically lower mortality rates than one-star hospitals.

Selective referral strategies have other downsides. Strategies that displace patients from their usual site of care and regular physicians may interfere with coordination of care. They tend to be highly polarizing, dividing hospitals and surgeons into winners and losers. In alienating the latter, a price of selective referral may be lost opportunities for engaging physicians in other types of quality improvement efforts. And finally, selective referral improves outcomes exclusively to the extent that it steers care away from poor performers. It provides no mechanism for helping other hospitals and surgeons improve their outcomes.

PROCESS COMPLIANCE

- Another approach to improving surgical outcomes is to encourage hospitals and surgeons to increase their compliance with processes of care associated with better outcomes. This model is best represented by ongoing pay-for-performance programs of both public and private payers. For example, payers are linking hospital reimbursement to satisfactory adherence to evidence-based practices related to perioperative care, as defined by the Surgical Care Improvement Project (SCIP), a joint effort of the Centers for Medicare and Medicaid Service (CMS) and the Centers for Disease Control and Prevention.¹⁵ At the present time,

these include specific processes aimed at reducing rates of surgical site infection, postoperative cardiac events, venous thromboembolism, and ventilator-associated pneumonia.

Efforts aimed at improving compliance with specific processes of care are considerably less polarizing than selective referral. In theory, anyone can "win." To the extent that surgeons can "play to the quiz," process-based pay-for-performance programs have the potential to achieve rapid and significant improvements in many aspects of perioperative care. At the University of Michigan Hospital, for example, the proportion of colorectal surgery patients receiving an appropriate antibiotic within 60 minutes prior to incision increased virtually overnight, from 70% to over 95%, following implementation of a pay-for-performance program by one of its major private payers. Studies in primary care suggest that pay-for-performance programs may be particularly effective in improving process compliance among poor performers and thus reducing overall variation.^{16,17}

- Nonetheless, the extent to which process compliance will improve surgical outcomes remains uncertain. Studies to date have generally failed to demonstrate a strong relationship between provider performance and specific process measures and patient outcomes. For example, based on data suggesting that patients in whom more nodes are detected seem to have a more favorable prognosis after cancer surgery, many pay-for-performance programs recently began rewarding hospitals for examining at least 12 lymph nodes from the surgical specimens of patients undergoing colectomy for colon cancer. In a recent study, hospitals varied widely in their success in achieving the 12-node minimum.¹⁸ However, hospitals scoring well on this process measure had virtually identical 5-year survival rates as those scoring poorly. In another study by Hawn et al.,¹⁹ hospitals' compliance with SCIP-1 (proportion of patients receiving appropriate antibiotics within 60 minutes of surgical incision) had little relation to their rates of surgical site infection. Such studies highlight the complexity of surgical care and the limitations of focusing on a small number of discrete steps.

Even if current process compliance strategies were successful in reducing rates of specific complications, it is not certain that they would also reduce mortality, arguably the most important end result of many major procedures. To explore this issue empirically, we recently assessed hospital compliance with several process measures targeted by the Surgical Care

FIGURE 14.1. Association between overall hospital compliance with Surgical Care Improvement Project (SCIP) measures (from the Centers for Medicare and Medicaid Service's Hospital Compare Program) and risk-adjusted mortality rates with several high-risk procedures, based on 2005–2006 national Medicare data.

Improvement Project, as compiled by CMS's Hospital Compare Program. Process compliance varied widely across hospitals (56% in the lowest vs. 91% in the highest hospital tercile). However, hospital compliance with SCIP process measures had no significant relationship with perioperative mortality for high-risk surgery (Fig. 14.1).

- 4 Although prophylactic strategies aimed at avoiding complications in the first place have obvious appeal, “rescuing” patients once a complication has occurred may be even more critical in reducing mortality. In a large study of Medicare patients by Silber et al., hospital mortality with specific procedures seemed to be primarily related to failure to rescue (the likelihood of mortality given a complication), and only weakly correlated with complication rates.²⁰ We conducted a similar analysis based on data from the American College of Surgeons National Surgical Quality Improvement Program. Participating hospitals were ranked and sorted according to their risk-adjusted mortality rates. Hospitals in the best quintile had mortality rates of only 2.2%, versus 7.2% in the highest-mortality quintile. As seen in Figure 14.2, high-mortality hospitals had only slightly higher overall complication rates (odds ratio 1.2, $p < 0.001$) than low-mortality hospitals. However, their failure-to-rescue rates were markedly higher (odds ratio 3.2, $p < 0.001$).

OUTCOMES MEASUREMENT

In contrast to payers and regulators, professional organizations in surgery are focusing primarily on disseminating

FIGURE 14.2. Major complication rates and failure-to-rescue rates at hospitals in the lowest and highest quintiles of overall risk-adjusted mortality, based on 2005–2006 data from the American College of Surgeons' National Surgical Quality Improvement Program (NSQIP). OR, odds ratio.

nationwide systems for tracking surgical outcomes. Their goal is to provide hospitals and surgeons with rigorous feedback about their outcomes relative to those of their peers, in the hopes that they will identify opportunities for improvement and respond accordingly. This model is less prescriptive than the process compliance approach and assumes that hospitals and surgeons can decide best how to improve care at the local level.

The Society of Thoracic Surgeons was among the first to embrace this model and now a large majority of U.S. hospitals involved in cardiac surgery contribute to its national outcomes database.²¹ First developed by the Department of Veterans Affairs, the NSQIP has been adapted for use in the private sector by the ACS and has become the most recognized outcomes measurement platform for noncardiac surgery.^{10,22} Although the ACS's NSQIP has traditionally assessed morbidity and mortality for random samples of patients undergoing any major procedures, the program will soon begin procedure-specific data collection and outcomes reporting.²³

This model of centralized quality measurement but local quality improvement has particular appeal among surgeons. They view good outcomes as the best criterion of surgical quality, but do not like directives about how to achieve them. There is strong evidence that this model can be very effective in reducing both overall mortality and variation across providers. In northern New England, for example, mortality with coronary artery bypass grafting fell by more than 25% almost immediately following feedback of mortality data to hospitals and surgeons; variation in mortality rates across hospitals fell even more dramatically.²⁴ This surgical “Hawthorne effect” has been similarly observed in Veterans Affairs hospitals nationwide after implementation of the NSQIP.⁴ Although what actually changed about clinical practice to effect this improvement has never been fully characterized, overall morbidity rates fell by over 40%.

Among their disadvantages, outcomes measurement programs often involve extensive data collection (mainly to ensure adequate risk adjustment) and thus can be expensive. Annual costs for hospitals participating in the ACS's NSQIP exceed \$100,000. Outcomes measures, particularly when assessed at the level of specific procedures, are often hindered by small sample sizes and too “noisy” to inform hospitals and surgeons of their true performance.²⁵ Type I and type II errors can lead to oversteering and understeering, respectively, in targeting quality improvement efforts. Finally, outcomes measurement provides no insights about best practices and how individual providers or the profession as a whole can improve. Outcomes feedback alone may also be insufficient for addressing specific types of quality problems, including surgeon inexperience, technical proficiency, and judgment.

SUMMARY

6 Selective referral, process compliance, and outcomes measurement reflect different philosophies on how best to improve surgical quality and have distinct advantages and disadvantages. The optimal strategy may depend on political realities, the clinical context (e.g., which procedure), and which outcomes stakeholders hope to improve.⁹ As currently configured, selective referral strategies may be best applied to relatively uncommon procedures for which outcomes vary dramatically across hospitals and surgeons (e.g., esophagectomy, pancreatic resection). Process compliance strategies are currently focusing on “low-hanging fruit”—improving adherence to a small number of evidence-based practices in perioperative care. They may not be effective in reducing surgical mortality, but they may ultimately prove successful to reducing adverse events important to patients (e.g., surgical site infection). Finally, outcomes measurement efforts—the major thrust of professional organizations—are likely to improve outcomes to the extent that they can capitalize on the surgical Hawthorne effect. In addition to spurring quality improvement at the local level, these efforts may ultimately provide a platform for public reporting and provider accountability in surgery.

Each of the three strategies would benefit from advances in quality measurement and improvement. Selective referral could be improved by measures that more reliably capture performance for individual hospitals and surgeons. Optimal measures would not only describe past performance, but also forecast future outcomes for patients and payers trying to identify the best hospitals and surgeons for specific procedures. As described elsewhere, individual measures of structure (including procedure volume), process of care, and outcomes have major limitations in reflecting provider-specific quality.²⁶ Composite quality measures, which empirically combine information from several quality domains, appear very promising and may soon become the standard in selective referral.^{27,28} Simple composites combining procedure volume and operative mortality have already been adopted by the Leapfrog Group.

Effective process compliance strategies await higher-leverage processes of care on which to base them. A better understanding of mechanisms underlying variation in surgical mortality and other important outcomes is essential for identifying such practices. For example, which types of clinical events and complications account for differences in mortality across hospitals? Which specific processes of care and organizational factors explain different rates of these clinical events? Previous research provides only preliminary answers to these basic questions. High-leverage processes of care may ultimately prove harder to codify than the perioperative processes that SCIP and payers are now focusing upon, and may involve those related to preoperative decision making (e.g., which patients to operate on in the first place) and surgeon proficiency in the operating room.

To fully realize their potential, outcomes measurement strategies need a more potent “effector arm.” Performance feedback may be the essential first step, but hospitals and surgeons need more guidance on what they can do to improve. As described earlier, a better understanding of mechanisms underlying variation and suboptimal outcomes will be crucial in this regard. In the meantime, professional organizations should develop better systems for developing and disseminating practice guidelines, providing expert-based consultative services to underperforming providers, and educating surgeons about the principles of continuous quality improvement.

Regardless of the underlying improvement strategy, payers and professional organizations should ensure that surgical quality is not defined too narrowly. At the present time, each is focusing almost exclusively on measures of technical quality around the surgical episode. However, a large body of evidence suggests that the use of surgery varies even more widely across providers than do the outcomes of surgery. Despite the practical and methodologic challenges involved, policy approaches to improving

surgical care will eventually need to consider appropriateness and the quality of the decision to operate in the first place.

CHAPTER 15 ■ MEASURING THE QUALITY OF SURGICAL CARE

JUSTIN B. DIMICK AND JOHN D. BIRKMEYER

KEY POINTS

- 1 The National Quality Forum (NQF) has recently emerged as the leading organization endorsing quality measures. Many other organizations, including the Joint Commission and the Centers for Medicare and Medicaid Services (CMS), rely on endorsement by the NQF before applying a measure to practice.
- 2 Quality measures fall into three categories: structure, process, and outcomes. Health care structure refers to fixed attributes of the system in which patients receive care. Process of care measures are the clinical details of care provided to patients. Outcome measures reflect the end result of care, from a clinical perspective or as judged by the patient.
- 3 Composite measures, created by combining multiple individual quality indicators, are becoming increasingly used in the assessment of surgical quality. Most existing pay-for-performance efforts, including the CMS pilot, use composite measures to assess the quality of medical and surgical diagnoses.
- 4 No quality measure is perfect. Clinical leaders, patient advocates, payers, and policy makers will have to make decisions about when imperfect measures are good enough to act upon. A measure should be implemented only with the expectation that acting on it will result in a net improvement in health quality.
- 5 It is important to ensure a good match between the performance measure and the primary goal of measurement. The right measure depends on whether the underlying goal is (a) quality improvement or (b) selective referral—directing patients to higher-quality hospitals and/or providers.
- 6 For quality improvement purposes, a good performance measure must be actionable. Measurable improvements in the given process should translate to clinically meaningful improvements in patient outcomes.
- 7 With selective referral, a good measure will steer patients to better hospitals or physicians. As one basic litmus test, a measure based on prior performance should reliably identify providers likely to have superior performance now and in the future.
- 8 One of the biggest limitations of surgical quality measurement is the statistical “noise” from the small sample sizes at most hospitals. This problem makes it difficult to isolate the quality signal from the background statistical noise. An emerging technique, reliability adjustment, directly addresses this problem. This technique, based on hierarchical modeling, quantifies and subtracts statistical noise from the measurement process.
- 9 Another significant limitation of existing approaches to surgical quality assessment is a lack of good measures of global quality. As payers and purchasers of health care move forward with value-based purchasing, there is a growing need for better composite scores. In this chapter, we discuss an emerging technique for creating empirically weighted composite measures of surgical performance.
- 10 An emerging technique for creating empirically weighted composite measures of surgical performance is improving the quality and efficiency of surgical care. Quality measures are only useful if they inform improvement efforts. Future refinements in measurement should therefore aim to meet the diverse needs of the improvement efforts of patients, payers, and providers.

With growing recognition that the quality of surgical care varies widely, good measures of performance are in high demand. Patients and their families need accurate information to help them choose the safest hospitals for surgery.¹ Employers and payers need reliable measures for their value-based purchasing programs.² Motivated in part by these external pressures, clinical leaders need better measures to guide their quality improvement efforts.³

Despite a broadening array of measures, there remains considerable uncertainty about which measures are most useful.^{4,5} Current measures are remarkably heterogeneous, encompassing different elements of health care structure, process, and outcomes. With the proliferation of value-based purchasing, which requires a global assessment of quality, there has been a rapid growth in the use of composite measures.⁶ Although each of these types of performance measures has strengths, each is also associated with conceptual, methodologic, and/or practical problems (Table 15.1).

This chapter provides an overview of existing quality indicators followed by a review of the main strengths and limitations of each type of measure: structure, process, outcomes,

and composites. The chapter then closes with recommendations for selecting the right measure and a description of emerging techniques that address some of the limitations of existing quality measures.

OVERVIEW OF CURRENT MEASURES

- 1 An ever-broadening array of performance measures has been developed for assessing surgical quality. Over the past few years, the National Quality Forum (NQF) has emerged as the leading organization endorsing quality measures. Table 15.2 includes surgical quality measures endorsed by the NQF. Many other organizations, including the Joint Commission and the Centers for Medicare and Medicaid Services (CMS), rely on endorsement by the NQF before applying a measure to practice. The number of measures relevant to surgery endorsed by the NQF has grown rapidly. Many of these new measures are part of CMS's Surgical Care Improvement Program (SCIP), which includes process measures related to prevention of

TABLE 15.1

EXAMPLES, STRENGTHS, AND LIMITATIONS OF DIFFERENT APPROACHES TO MEASURING SURGICAL PERFORMANCE

	■ EXAMPLE	■ STRENGTHS	■ LIMITATIONS
Structure	Hospital or surgeon volume Surgeon specialty training	Inexpensive and readily available Strong relationship to important outcomes	Not actionable for quality improvement Not good at discriminating individual provider performance
Process	Appropriate selection, timing, and duration of antibiotic prophylaxis Use of internal mammary artery for coronary artery bypass grafting	Actionable as targets for improvement Everybody can achieve 100% compliance	Most known processes relate to secondary outcomes High-leverage processes are unknown for most procedures
Outcome	Risk-adjusted mortality Risk-adjusted morbidity	Seen as the bottom line of patient care Buy-in from providers	Sample sizes too small at individual hospitals
Composite	The Leapfrog Group's Survival Predictor STS Composite score for coronary artery bypass grafting	Addresses problems with small sample size Makes sense of multiple conflicting measures	Too broad to identify specific areas that need improvement

STS, Society of Thoracic Surgeons.

TABLE 15.2

OVERVIEW OF CLINICAL PERFORMANCE MEASURES RELEVANT TO SURGERY THAT HAVE BEEN ENDORSED BY THE NATIONAL QUALITY FORUM (NQF) AS OF AUGUST 2007

■ DIAGNOSIS OR PROCEDURE	■ PERFORMANCE MEASURE
Coronary artery bypass	Use of internal mammary artery Preoperative beta-blocker Deep sternal wound infection rate Prolonged intubation Renal insufficiency Surgical re-exploration Hospital volume
Aortic valve replacement	Risk-adjusted mortality rate Hospital volume
Mitral valve replacement	Risk-adjusted mortality rate Hospital volume
Any cardiac surgery	Antiplatelet, antilipid, and beta-blockers on discharge Participation in a cardiac surgery registry Preoperative beta-blocker Renal insufficiency Prolonged intubation Stroke
Surgery for breast cancer	Radiation therapy after breast conservation surgery
Surgery for colon cancer	Adjuvant chemotherapy for appropriate candidates At least 12 lymph nodes identified in surgical specimen
Surgery for rectal cancer	Adjuvant radiation therapy for patients with rectal cancer
Any surgical procedure	Venous thrombosis prophylaxis Appropriate timing, selection, and discontinuation of prophylactic antibiotics
Any hospitalized patient, including all after surgery	Central venous catheter infection rate Urinary catheter-associated infection rate Ventilator-associated pneumonia rate

TABLE 15.3**OVERVIEW OF PERFORMANCE MEASURES CURRENTLY USED FOR SURGERY**

■ DIAGNOSIS OR PROCEDURE	■ PERFORMANCE MEASURE	■ DEVELOPER/ENDORSER
Critically ill patients	Board-certified intensivist staffing	LF
Abdominal aneurysm repair	Hospital volume	AHRQ, LF
	Risk-adjusted mortality rates	AHRQ
	Prophylactic beta-blocker use	LF
Carotid endarterectomy	Hospital volume	AHRQ
Esophageal resection for cancer	Hospital volume	AHRQ
Pancreatic resection	Hospital volume	AHRQ, LF
	Risk-adjusted mortality rates	AHRQ
Pediatric heart surgery	Hospital volume	AHRQ
	Risk-adjusted mortality rates	AHRQ
Hip replacement	Risk-adjusted mortality rates	AHRQ
Craniotomy	Risk-adjusted mortality rates	AHRQ
Cholecystectomy	Laparoscopic approach	AHRQ
Appendectomy	Avoidance of incidental appendectomy	AHRQ

AHRQ, Agency for Healthcare Research and Quality; LF, Leapfrog Group.

surgical site infections, postoperative cardiac events, venous thromboembolism, and respiratory complications.

While the NQF is the central organization for evaluating candidate measures, many other organizations continue to create their own quality indicators (Table 15.3). The Agency for Healthcare Research and Quality (AHRQ) has focused on quality measures that can be used with administrative data. For example, the AHRQ maintains and distributes state and national administrative data as part of their Healthcare Cost and Utilization Project (HCUP). Processes of care are generally not available in these datasets, so the AHRQ measures focus mainly on structure (e.g., hospital volume) and outcomes (e.g., mortality rates).

The Leapfrog Group, a coalition of large employers and health care purchasers, has issued perhaps the most visible set of surgical quality indicators for its value-based purchasing initiative. Although originally focused exclusively on structural measures, including volume standards, their current standards also include selected processes and risk-adjusted outcomes. In the future, the Leapfrog Group will use a composite of operative mortality and hospital volume as the primary measure for their evidence-based hospital referral initiative.⁷ We will discuss composite measures in detail later in this chapter.

INDIVIDUAL QUALITY MEASURES

- Quality measures fall into three categories: structure, process, and outcomes.

Structure

Health care structure refers to fixed attributes of the system in which patients receive care. Many structural measures describe hospital-level attributes, such as the resources or staff coordination and organization (e.g., nurse-to-patient ratios, hospital teaching status). Other structural measures reflect attributes of individual physicians (e.g., subspecialty board certification, procedure volume).

Strengths. Structural measures of quality have several attractive features. First, they are strongly related to patient outcomes. For example, with esophagectomy and pancreatic resection, operative mortality rates at high-volume hospitals are often 10% lower, in absolute terms, than low-volume centers.^{8,9} In some instances, structural measures such as procedure volume are more predictive of subsequent hospital performance than any known processes of care or even direct mortality measures (Fig. 15.1).

Perhaps the most important advantage of structural variables is the ease with which they can be assessed. Many can be determined using readily available administrative data. Although some structural measures require surveying hospitals or providers, such data are much less expensive to collect than measures requiring detailed patient-level information.

Limitations. Perhaps the greatest limitation of this approach is that structural measures are not readily actionable. For example, a small hospital cannot readily make itself a high-volume center. Thus, while selected structural measures may be useful for selective referral initiatives, they have limited value for quality improvement purposes. Structural measures are also limited in their ability to discriminate the performance of individual providers. For example, in aggregate, high-volume hospitals have much lower mortality rates than lower-volume centers for pancreatic resection.^{8,9} However, some individual high-volume hospitals may have high mortality rates, and some low-volume hospitals may have low mortality rates.¹⁰ Although the true performance of individual hospitals is difficult to confirm empirically (for sample size reasons), this lack of discrimination is one reason structural measures are often viewed as “unfair” by many providers.

Process of Care

Process of care measures are the clinical details of care provided to patients. Although long the predominant quality indicators for medical care, their popularity in surgery is growing rapidly. Perhaps the best example of the trend toward using

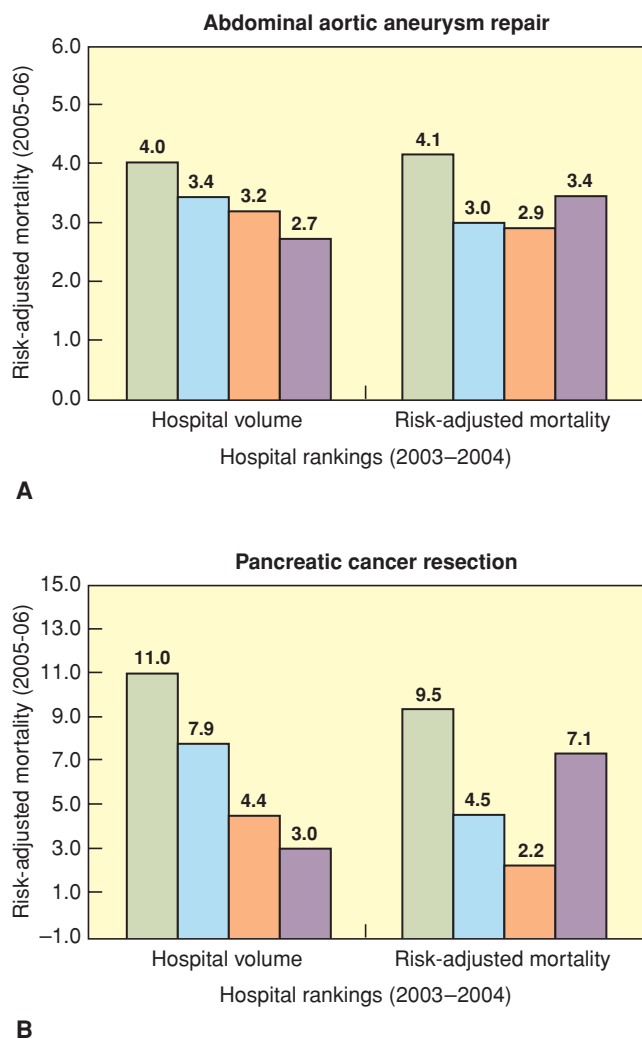

FIGURE 15.1. Ability of hospital rankings based on 2003–2004 mortality rates and hospital volume to predict risk-adjusted mortality in 2005–2006. Data shown for abdominal aortic aneurysm repair (A) and pancreatic cancer resection (B). Source: National Medicare data.

process measures is the CMS's SCIP. As previously mentioned, this quality measurement initiative focuses exclusively on processes related to prevention of surgical site infections, post-operative cardiac events, venous thromboembolism, and respiratory complications.

Strengths. Since processes of care reflect the care actually delivered by physicians, they have face validity and enjoy greater buy-in from providers. They are also directly actionable and provide good substrate for quality improvement activities. Although risk adjustment may be important for outcomes, it is not required for many process measures. For example, the appropriate prophylaxis against postoperative venous thromboembolism is a widely used process measure. Since virtually all patients undergoing open abdominal surgery should be offered some form of prophylaxis, there is little need to collect detailed clinical data for risk adjustment.

Limitations. The biggest limitation of process measures is the lack of correlation between processes of care and important outcomes.⁴ There is a growing body of empirical data showing very little correlation between processes of care and important outcomes.^{11–13} Most data come from literature on medical diagnoses, such as acute myocardial infarction. For example, the Joint Commission and CMS process measures

for acute myocardial infarction explained only 6% of the observed variation in risk-adjusted mortality for acute myocardial infarction.¹²

Although few analogous studies have been done in surgery, there are some reasons to believe that existing process measures explain very little of the variation in important surgical outcomes. First, most process measures currently used in surgery relate to secondary outcomes. While none would dismiss the value of prophylactic antibiotics in reducing risks of superficial wound infection, this process is not related to the most important adverse events of major surgery, including death.

Second, process measures in surgery often relate to complications that are very rare. For example, there is consensus that venous thromboembolism prophylaxis is necessary and important. The SCIP measures, endorsed by the NQF, include the use of appropriate venous thrombosis prophylaxis. However, pulmonary embolism is very uncommon, and improving adherence to these processes will therefore not avert many deaths. Until we understand which processes of care account for those adverse events leading to death, process measures will have limited usefulness in surgical quality measurement.^{4,11–13}

Outcomes

Outcome measures reflect the end result of care, from a clinical perspective or as judged by the patient. Although mortality is by far the most commonly used measure in surgery, other outcomes that could be used as quality indicators include complications, hospital readmission, and a variety of patient-centered measures of quality of life or satisfaction. The best example of this type of measurement is found in the National Surgical Quality Improvement Program (NSQIP).¹⁴ The NSQIP is a surgeon-led clinical registry for feeding back risk-adjusted morbidity and mortality rates to participating hospitals. After its successful implementation in Veterans Affairs (VA) hospitals, it was introduced into the private sector with good results.¹⁵ Under the guidance of the American College of Surgeons, hospital participation in the NSQIP continues to grow, with more than 200 hospitals currently participating. Several changes to the NSQIP measurement platform, which were discussed in the previous chapter, will help make the program less expensive and more useful.³

Strengths. There are at least two key advantages of outcomes measures. First, outcome measures have obvious face validity, and thus are likely to get the greatest “buy-in” from hospitals and surgeons. Surgeon enthusiasm for the NSQIP and the continued dissemination of the program clearly underline this point. Second, the act of simply measuring outcomes may lead to better performance—the so-called Hawthorne effect. For example, surgical morbidity and mortality rates in VA hospitals have fallen dramatically since implementation of the NSQIP two decades ago.¹⁴ No doubt many surgical leaders at individual hospitals made specific organizational or process improvements after they began receiving feedback on their hospitals' performance. However, it is very unlikely that even a full inventory of these specific changes would explain such broad-based and substantial improvements in morbidity and mortality rates.

Limitations. Hospital- or surgeon-specific outcome measures are severely constrained by small sample sizes. For the large majority of surgical procedures, very few hospitals (or surgeons) have sufficient adverse events (numerators) and cases (denominators) for meaningful, procedure-specific measures of morbidity or mortality. For example, Dimick et al. used data from the Nationwide Inpatient Sample to study seven procedures for which mortality rates have been advocated as quality indicators by the AHRQ.¹⁶ For six of the seven procedures, a very small proportion of US hospitals had adequate caseloads to rule out a mortality rate twice the national average (Fig. 15.2). Although

FIGURE 15.2. Big problems with small samples: the proportion of hospitals in the United States with sufficient caseloads (sample size) to reliably use mortality rates to measure quality.

identifying poor-quality outliers is an important function of outcomes measurement, focusing on this goal alone significantly underestimates problems with small sample sizes. Discriminating among individual hospitals with intermediate levels of performance is even more difficult.

Another significant limitation of outcomes assessment is the expense of data collection. Reporting outcomes requires the costly collection of detailed clinical data for risk adjustment. For example, it costs over \$100,000 annually for a private sector hospital to participate in the NSQIP. Because of the expense of data collection, the American College of Surgeons' (ACS's) NSQIP currently collects data on only a sample of patients undergoing surgery at each hospital. Although this sampling strategy decreases the cost of data collection, it exacerbates the problem of small sample size with individual procedures. As discussed in the next chapter, changes in the next iteration of the NSQIP are aimed at reducing the expense of data collection without compromising the risk adjustment.

COMPOSITE MEASURES

- 3 Composite measures, created by combining multiple individual quality indicators, are becoming increasingly used in the assessment of surgical quality.^{6,7,17} Most existing pay-for-performance efforts, including the CMS pilot, use composite measures to assess the quality of medical and surgical diagnoses. The Society of Thoracic Surgeons (STS) Measurement Taskforce has created a new composite score that combines elements of outcomes and processes of care into a single measure.¹⁷ With growing enthusiasm for this approach, the AHRQ recently published a technical review of composite measures.¹⁸

Strengths

Composite measures have two main advantages over individual quality indicators. First, pooling multiple measures overcomes the problem with small sample sizes described earlier. Second, this approach deals with the problem of multiple conflicting measures, and simplifies quality measurement by providing a single, summary measure of performance. For example, the STS measure for cardiac surgery combines several measures of process and outcomes to create a single score with three categories: one star, two stars, and three stars.¹⁷

Limitations

Composite measures have both technical and practical limitations. Perhaps the biggest technical challenge is weighting the

input measures. Most existing composite measures are created using equal weighting, expert opinion, or the "all or none" approach. For example, the STS cardiac surgery composite score calculates a domain-specific score for morbidity, mortality, process of care, and perioperative medications, and then places equal weight on each domain.¹⁷ Unfortunately, these simplistic weighting schemes do not take into account the simple fact that some measures are more important than others. Ideally, input measures would be weighted empirically, based on how strongly they are related to important outcomes.¹⁸ An emerging technique for creating such empirically weighted composite measures of surgical performance will be discussed at the end of the chapter.¹⁹

Composite measures also have a practical limitation. By design, composite measures reflect global performance with a procedure or specialty. It is hard to know exactly where improvement is needed with this global assessment. Thus, it is important to deconstruct the composite measures into the individual process and outcome measures. Actionable targets for improvement (e.g., high complication rates or failure to adhere to specific processes) can then be addressed.

CHOOSING THE RIGHT MEASURE

- 4 No quality measure is perfect. Clinical leaders, patient advocates, payers, and policy makers will have to make decisions about when imperfect measures are good enough to act upon. A measure should be implemented only with the expectation that acting on it will result in a net improvement in health quality. Thus, the direct benefits of implementing a particular measure cannot be outweighed by the indirect harms. Unfortunately, these benefits and harms are often difficult to measure and heavily influenced by the specific context and who—patients, payers, or providers—is doing the accounting. For this reason, there is no simple answer for where to "set the bar."
- 5 It is important to ensure a good match between the performance measure and the primary goal of measurement. The right measure depends on whether the underlying goal is (a) quality improvement or (b) selective referral—directing patients to higher-quality hospitals and/or providers. Although many pay-for-performance initiatives have both goals, one often predominates. For example, the ultimate objective of the CMS's pay-for-performance initiative with prophylactic antibiotics is improving quality at all hospitals (quality improvement). Conversely, the Leapfrog Group's efforts in surgery are primarily aimed at getting patients to hospitals likely to have the best outcomes (selective referral).
- 6 For quality improvement purposes, a good performance measure must be actionable. Measurable improvements in the given process should translate to clinically meaningful improvements

in patient outcomes. Although quality improvement activities are rarely “harmful,” their major downsides relate to their opportunity cost. Initiatives hinged on bad measures divert resources (e.g., time and focus of physicians and other staff) away from more productive activities.

7 With selective referral, a good measure will steer patients to better hospitals or physicians. As one basic litmus test, a measure based on prior performance should reliably identify providers likely to have superior performance now and in the future. At the same time, an ideal measure would not incentivize perverse behaviors (e.g., surgeons doing unnecessary procedures to meet a specific volume standard) or negatively affect other domains of quality (e.g., patient autonomy, access, and satisfaction).

Many believe that a good performance measure must discriminate performance at the individual level. From the provider perspective in particular, a “fair” measure must reliably reflect the performance of individual hospitals or physicians. Unfortunately, as described earlier, small caseloads (and sometimes case mix variation) conspire against this objective for most procedures. Patients, however, should value information that improves their odds of good outcomes on average. Many measures meet this latter interest while failing on the former (e.g., hospital volume standards). There may be no simple solution to resolving the basic tension implied by performance measures that are unfair to providers yet informative for patients. However, it underscores the importance of being clear about both the primary purpose (quality improvement or selective referral) and whose interests are receiving top priority (provider or patient).

DEVELOPING BETTER MEASURES

8 Although great progress has been made, the science of quality measurement is in its infancy. In fact, there are solutions on the horizon for many of the limitations discussed earlier. One of the biggest limitations of surgical quality measurement is the statistical “noise” from the small sample sizes at most hospitals. This problem makes it difficult to isolate the quality signal from the background statistical noise. In other words, it is often hard to know whether hospitals or surgeons have poor performance because they provide low-quality care or because they were unlucky. For obvious reasons, labeling surgeons and hospitals correctly is extremely important.

An emerging technique, reliability adjustment, directly addresses the problem of statistical noise.²⁰ This technique, based on hierarchical modeling, quantifies and subtracts statistical noise from the measurement process. Essentially, it “shrinks” providers’ performance back toward average unless they deviate to such an extreme that it is safe to assume they are truly different. In this way, it gives providers the benefit of the doubt. Figure 15.3 shows the risk-adjusted mortality rates for pancreatic resection in Medicare patients before and after reliability adjustment. Prior to reliability adjustment, the mortality rates varied from 0% to 100%. After reliability adjustment, the mortality rates only vary from 2% to 22%, yielding a range of performance that is clinically more realistic. Reliability adjustment is gaining popularity outside surgery (e.g., ambulatory care) and is becoming widely recognized as a valid tool for improving the accuracy of quality measurement.^{20,21}

Despite wide use in other fields, reliability adjustment is only beginning to find application in surgery. Perhaps the most prominent example is the Massachusetts state cardiac surgery report card, which publishes “smoothed” mortality rates for each hospital.²² These are obtained with reliability adjustment using hierarchical modeling techniques, as described earlier. This approach will also soon be applied to the morbidity and mortality rates in the ACS’s NSQIP, as described with other changes in a recent “Blueprint” for a new ACS NSQIP.³ As the

FIGURE 15.3. Variation in hospital mortality rates before and after adjusting for reliability. Twenty randomly sampled hospitals are shown. Source: National Medicare data, 2005–2006.

advantages of this technique become more widely known, there is no doubt it will become the standard technique for reporting risk-adjusted outcomes.

9 Another significant limitation of existing approaches to surgical quality assessment is a lack of good measures of global quality. As payers and purchasers of health care move forward with value-based purchasing, there is a growing need for better composite scores. Unfortunately, as discussed earlier, most approaches are not thoughtful about how they weight input measures. However, there is an emerging technique for creating empirically weighted composite measures of surgical performance.¹⁹ To create these measures, a “gold standard” quality measure is first identified (e.g., risk-adjusted mortality). The relationships between all input measures and this “gold standard” measure are then determined. A composite is then created that weights the input measures based on how reliable they are (a measure of precision) and how closely they are related to the “gold standard” outcome. Staiger et al. recently published the methods for creating these measures using aortic valve replacement.¹⁹ They found that a composite measure of risk-adjusted mortality and hospital volume with aortic valve replacement combined with risk-adjusted mortality for other cardiac procedures explained 70% of the hospital-level variation in mortality and was better at predicting future performance than any individual measure (Fig. 15.4).

Although both of these emerging techniques will enhance our ability to profile hospitals on technical quality, we also need to develop better measures of surgical decision making. Wide geographic variations in the use of surgical procedures imply substantial underuse, misuse, and overuse. Escalating health care costs are at least in part due to overuse and misuse of surgical interventions. Measures of appropriateness or utilization will need to become part of our armamentarium if meaningful attempts at reducing these variations are to be made. Although appropriateness criteria have been extensively studied, there is growing consensus that they are impractical on a large scale.²³ The task of tabulating all of the potential scenarios in which a procedure is “appropriate” or “inappropriate” is daunting. Even when these exhaustive lists are created, reasonable clinicians may still disagree in a large proportion of cases.²³ Appropriateness criteria should be limited to “low-hanging fruit,” those procedures with a few, well-agreed-upon indications for operation.

For the majority of procedures, however, another approach is needed. One promising approach is the measurement of

FIGURE 15.4. Ability of various historical (2000–2001) quality indicators to forecast subsequent (2002–2003) risk-adjusted mortality with aortic valve replacement (AVR). Hospitals sorted into quintiles according to hospital volume alone, risk-adjusted mortality alone, and composite measure based on AVR mortality, AVR hospital volume, and mortality and volume with other cardiac procedures.

utilization at the level of the Physician-Hospital Network (PHN). The PHN is a virtual organization for physicians and the hospital with which they are affiliated.^{24,25} PHNs are felt by some health policy experts to be the right level of accountability for measuring the quality of the extended health care system. Rates of surgery for each PHN could be used for public reporting, value-based purchasing, or tiered health plans. This approach would allow patients to choose hospitals based on how “aggressive” they are. Public disclosure of surgery rates would also put downward pressure on hospitals with high rates of surgery, potentially discouraging expanding capacity when it may not be necessary.

The near future will no doubt bring other major advances in the science of quality measurement. The accelerating pace of technology will surely play a role. As electronic medical records become more widely adopted, clinical data will be more easily abstracted from the patient record. Such improvements in technology will provide cost-efficient risk adjustment and more practicable approaches for assessing the adherence to important processes of care. While improvements in technology and infrastructure are of great benefit, involvement of surgeons in health services research will also be important. Studies using tools of clinical epidemiology are needed to generate evidence linking high-leverage processes of care to important outcomes. These processes of care could then be applied to existing quality measurement platforms. Surgeon-scientists with scholarship in quality improvement will be instrumental in providing these insights and leading this high-impact academic field forward.

10 When measuring quality, it is important to keep in mind the ultimate goal: improving the quality and efficiency of surgical care. Quality measures are only useful if they inform improvement efforts. Future refinements in measurement should therefore aim to meet the diverse needs of the improvement efforts of patients, payers, and providers. In the previous chapter, the three dominant approaches for improving surgical quality were discussed: selective referral, process compliance, and outcomes measurement. These three policy approaches roughly mirror the three types of quality measures (structure, process, and outcomes), providing real-world examples of how various stakeholders weigh the pros and cons of quality indicators, and ultimately choose an assessment approach by matching the measure to the purpose.

CHAPTER 16 ■ PATIENT SAFETY

DARRELL A. CAMPBELL, Jr.

KEY POINTS

- 1 Safety means “freedom from harm”; in the context of patient care, safety means freedom from harm associated with any medical action or treatment.
- 2 Even though the system should be constructed to back up human fallibilities, it is instructive to recognize these fallibilities. This subject is hard to quantify, but a good list, developed in a family practice environment, reads as follows: hurry, distraction, lack of knowledge, premature closure of the diagnostic process, and inadequate aggressiveness in patient management.
- 3 In the acute hospital setting, as opposed to the outpatient environment in family practice, safety problems typically involve poor handoffs, failures of teamwork, excess workload, and fatigue.
- 4 Another approach to the implementation of safe practices is to educate and train physicians and nurses within the context of a team.
- 5 The future of the patient safety movement depends on the development of an effective safety reporting mechanism.

IMPORTANT DEFINITIONS: SAFETY VERSUS QUALITY

The terms *quality* and *safety* have important bearings on any discussion of patient care. These are related subjects but have different meanings, and these differences should be underscored before any dialogue about patient safety begins. Safety means “freedom from harm”; in the context of patient care, safety means freedom from harm associated with any medical action or treatment. Quality is a more global term referring to a “degree of excellence.” It is theoretically possible for a hospital to be safe but for quality to be average or poor. It is not possible for a hospital to be of high quality and unsafe. In this chapter we focus primarily on the subject of patient safety, but admit that some aspects of the subject drift into the area of quality as well.

THE PROBLEM

By now, all are familiar with the report issued by the Institute of Medicine (IOM) in 2000 entitled *To Err Is Human*.¹ The report was an exhaustive review of the status of safety in our nation’s hospitals. The bottom line—which served as a “burning platform” for the patient safety movement—was the astonishing calculation that between 44,000 and 98,000 Americans died annually in hospitals as the result of preventable medical error. The report produced a flurry of outrage from consumer groups and denials and refutations from medical groups, but when the dust settled, what was left was the recognition, by all groups, that something was seriously wrong in our medical care delivery system.

Comparisons are often made between the safety of airline travel and medical care. One airline disaster every 2 or 3 years produces calls for new regulation, better airports, more frequent mechanical checks, and earlier retirement for pilots. But consider medical care. If even the lower number of preventable deaths extrapolated by the IOM report (44,000 annually) were seen as accurate, and one accepted that an average of 350 passengers were on board every major commercial aircraft flight, deaths from medical error would be equivalent of 63 separate midair collisions per year in the airline industry, or five per

month. Imagine the public outcry this would produce, the laws that would be quickly passed, and the boon to train travel that would result. But this is not what has happened in medicine. The government response has been weak at best, and the medical community has been slow to acknowledge, and even slower to respond, to the safety imperative.

CULTURE

Culture is defined as “how we do things around here.” That is, there is a certain level of acceptance for what goes on in a given hospital. That acceptance is based on two precepts, which in the past have not been challenged. One precept is that medical errors exist because “humans will always make mistakes.” While superficially true, this statement fails to acknowledge that modern human factors engineering strategies can militate against commonly encountered errors. A concrete example of how human factors engineering can be brought into play involves something as simple as a connector for medical tubing. If the connector is designed such that it is not possible to connect an O₂ line to a CO₂ valve, a potentially catastrophic mistake becomes impossible. More globally, work hour restrictions for medical trainees, which reduce fatigue, could be expected to result in fewer errors by exhausted and stressed doctors. To date, human factors engineering has not been brought into the delivery of medical care effectively. While humans will always be capable of making mistakes, the number of mistakes will be reduced if design is targeted to what we know about human fallibilities.

The second precept accounting for complacency is the notion that a medical error is the result of poor individual performance rather than an imperfect system of care. If an individual made the error, in isolation, the only thing to do about it would be to fire the hapless caregiver, or immerse him or her in intensive remedial education. The problem with this approach is that it doesn’t apply to the next hapless caregiver faced with the same situation. And so, since there is a high turnover in most medical environments, mistakes continue to happen, caregivers continue to be fired, and nothing really changes. This sequence has been ingrained in the medical culture, and is why the medical community has been slow to respond to the safety crisis.

Systems Failures

FIGURE 16.1. Systems failures.

SWISS CHEESE AND MEDICAL ERRORS

A popular paradigm in the medical safety area is the “Swiss cheese” model, introduced by James Reason² (Fig. 16.1). This model is a visual representation of the multiple system layers that could prevent a medical error from occurring. A beam of light, representing a latent error, passes through a hole in the cheese, which represents a system vulnerability. The latent error passing through the system via vulnerability will result in a medical error. If enough systems are set up with vulnerabilities, but in different locations, it becomes progressively harder for the latent error to become manifest clinically. The point here is that, while we recognize that both humans and systems of care have vulnerabilities, the prevention of error lies at the door of hospital leadership. Positive results come from the establishment of effectively redundant systems of error prevention. This concept is a major paradigm shift in the patient safety movement.

2 Even though the system should be constructed to back up human fallibilities, it is instructive to recognize these fallibilities. This subject is hard to quantify, but a good list, developed in a family practice environment, reads as follows: hurry, distraction, lack of knowledge, premature closure of the diagnostic process, and inadequate aggressiveness in patient management.³ The first three issues are probably obvious, but premature closure of the diagnostic process is a problem needing emphasis. Humans often fall into this trap. We see issues as black and white in an attempt to make sense out of complex circumstances. Hurry, distraction, and lack of knowledge contribute. Relevant pieces of Swiss cheese, which could counteract this tendency, include electronic diagnosis and decision-making aids; an institutional policy fostering physician interactions, teamwork, and second opinions; and setting and adhering to reasonable workload standards.

3 Depending on the environment, other fallibilities are exposed. In the acute hospital setting, as opposed to the outpatient environment in family practice, safety problems typically involve poor handoffs, failures of teamwork, excess workload, and fatigue.⁴

But what about the concept of individual responsibility? One cannot show up for work with a careless attitude, engage in irresponsible actions, and expect to be held unaccountable from poor performance because of the emphasis on systems. This is a delicate balance for any health care system. The underlying principle here is that most employees of a hospital wake up each morning wanting to do a good job, and to avoid mistakes, and hence (with exceptions) the general philosophy should be that a major improvement in safety will be at the level of system engineering rather than individual fallibility. When the onus of individual fallibility is lessened (not removed entirely), there then emerges a new sense of system responsibility, with increased willingness to identify system errors and to participate in safety enhancement as a group. This collaborative participation does not occur when one is worried about punitive consequences for reporting and the possibility of job loss.

LEADERSHIP AND POLICY

How does one change a culture? This is not done easily. There are two crucial elements, which, if effective, can change the culture direction positively. The first element is set by the example of hospital leadership. When the rank and file sees that the hospital CEO places patient safety at the top of the list and backs this priority up with funding, a lot of good things happen. When the CEO emphasizes a change in hospital policy, with an emphasis on safety, the change is reinforced. We introduced two policies that serve as examples to make this point. The first, the “full disclosure” policy, stipulated that employees were obligated (not just encouraged) to disclose fully to patients important errors made in rendering their care. Remarkably, this policy resulted in fewer malpractice claims against the system, but more important, it underscored for employees the institutional emphasis on openness and honesty.⁵ The second policy change implemented was the “speak up with safety concerns” policy, which stipulated that no caregiver could be punished for voicing a concern involving patient safety, regardless of feelings hurt or hierarchy violated. Again, this written policy clearly articulated a health system goal—that patient safety trumped all other considerations.

One manifestation of an improved safety culture is an increased error reporting rate. Clearly, the error reporting rate will not go up if there exists widespread fear of retribution for reporting. What is desired is an increased rate of error reporting, but a decreasing rate of events resulting in temporary or permanent harm. This pattern suggests that caregivers are vigilant, care about safety, and are reporting on “near misses.” The data from “near misses” represent a treasure chest of information that can be used to prevent actual mistakes. We have seen increased reporting in association with the purchase of a new electronic reporting format. Whether a change in culture or a change in reporting format is responsible for the increased level of reports is hard to say, but we believe that it is some combination of both (Fig. 16.2).

ASSESSING THE CULTURE

If one places priority on “improving” a safety culture, it is necessary that the “culture” can be measured. Validated culture surveys exist, which, if applied periodically in a hospital environment, give important insight into the success of safety culture initiatives. We use the Agency for Healthcare Research and Quality (AHRQ) safety culture instrument primarily and survey all caregivers at approximately 2-year intervals. We use the resulting information in three ways. First, we use the aggregate response to answer the question, “Are we improving the safety culture?” and, if not, “What are the areas that need to be addressed institutionally?” On our last survey, a clear sore point at our institution was difficulty with “handoffs,” that is, the transfer of information between caregivers and teams. We then developed a taskforce focused on fixing the problem, over

FIGURE 16.2. Overview of the reporting system.

both the short and long term. The long-term solution is an electronic one; the short-term solution is a paper-based handoff tool. This effort was a direct result of information gained from the safety culture survey.

A second way we use the safety culture survey data is to identify specific hospital units that are struggling with a dispirited or complacent attitude toward the safety effort. Such problems often result from poor nurse leadership, disruptive physicians, or a lack of perceived resources. Armed with information about the safety culture (or lack of it), the institution can implement a focused strategy customized to the problem. Figure 16.3 shows results from our survey arranged by individual nursing unit, demonstrating certain units in need of help with error reporting and, conversely, units where the culture is good and institutional resources are not needed. A third source of information derived from the survey comes from narrative comments entered by individual caregivers. This is a very rich source of information and, since it is anonymous, often draws a fine line under issues that are hard to talk about in any other forum. Issues of suspected physician impairment, abusive behavior, or lack of leadership skills are sometimes identified.

Two important questions regarding safety culture and our efforts to improve it remain. First, using the AHRQ tool, have we seen an aggregate improvement over the past two survey intervals? Many safety initiatives have been instituted over this period of time, and yet the aggregate culture data haven't shown much change. We interpret this information to mean that much more work needs to be done, and that changing a culture is a hard thing to do, akin to changing direction of an aircraft carrier. Also, over the period of time we have been studying our culture, our institutional activity has gone up dramatically, the complexity of our patients has increased, and nursing turnover has been high. Under these circumstances, no change in the safety culture data might be viewed more optimistically.

A second question is, Are there individual strategies we have used that influence the safety culture positively? If so, we could use these strategies more broadly. The answer to this question is yes. Patient safety rounds have been an important strategy that has improved the safety culture. Over the course

of the past several years, we have made safety rounds on over 125 occasions, at 2-week intervals. Safety rounds are carried out by leadership (chief of staff, chief of nursing, CEO, etc.) and a pointed 45-minute discussion ensues with the unit caregivers, including nurses, aides, clerks, and transporters. The culture effects of this endeavor are profound. When caregivers believe that leadership is willing to listen, takes safety very seriously, and will put resources behind the articulated concerns, an overall feeling of confidence and support of the safety effort follows. Figure 16.4 demonstrates that caregivers having participated in patient safety rounds viewed the patient safety environment much more positively than those who had not.

But is a positive safety culture actually associated with improved safety? The assumption is yes, but data were hard to come by until recently. In Michigan, a multihospital collaborative was initiated (the Keystone Project), the object of which was to implement evidence-based practices known to decrease the incidence of bloodstream infections (BSIs).⁶ One hundred and seven hospitals were involved, and caregivers responded to the Safety Attitudes Questionnaire (SAQ), similar to the AHRQ tool described previously. Results (incidence of BSIs) were correlated with answers to the SAQ. The results are seen in Figure 16.5. There was an important association noted between the best results (percent reduction in BSIs) and the most positive answers to SAQ questions. This is only an association (and subject to the usual caveats about associations vs. cause and effect), but important nonetheless. These results support the underlying hypothesis that when leadership prioritizes safety and implements actions to support safety, caregivers reflect this in their answers to the SAQ and this is associated with improved patient safety.

THE EVIDENCE BASE FOR PATIENT SAFETY

As important as it is to lay a strong foundation in safety culture, the energy and enthusiasm of caregivers to provide safe

FIGURE 16.3. Nonpunitive response to error.

patient care must be rooted in activities that have been found to be effective. Unfortunately, there does not exist at this point a large base of evidence in patient safety, largely because the field is relatively young. Recently, the World Health Organization (WHO) convened a group to carefully analyze existing studies and highlight effective strategies with an evidence base.⁷ These are listed in Table 16.1. Comments about specific evidence-based actions follow.

With regard to the administration of perioperative beta-blockers to prevent postoperative myocardial ischemia, it is very clear that patients already on such medications must be given them postoperatively. However, an initial interest in beta-blocker administration for patients never having received

them previously evaporated as the result of the POISE trial.⁸ This was an international randomized controlled trial focusing on this specific issue, and the result, after analyzing many thousands of patients, was that giving beta-blockers perioperatively to naïve patients caused more harm than good. Specifically, treated patients developed more troublesome bradycardia and hypotension than controls, and this resulted in a higher incidence of stroke, obviating the potential benefit of the drug in preventing myocardial ischemia.

Using maximum sterile barriers for central venous pressure (CVP) catheter insertion to prevent bloodstream infection may seem obvious, and the implementation of this protocol has resulted, in many studies, in a dramatic fall in the incidence of

FIGURE 16.4. Comparison of 2007 Agency for Healthcare Research and Quality (AHRQ) data participants versus nonparticipants in patient safety rounds.

FIGURE 16.5. Teamwork climate across Michigan intensive care units.

this complication. This strategy is complemented by the use of antibiotic-impregnated CVP catheter lines and the use of chlorhexidine in the daily maintenance of the insertion site. The use of ultrasound to help guide CVP catheter line insertion is clearly effective.

Prevention of the feared complication of ventilator-associated pneumonia is a very important consideration, since this development has a high fatality rate and is very expensive to treat. There is some evidence that the continuous aspiration of subglottic secretions is important. Our institution has been successful in decreasing the ventilator-acquired pneumonia rate dramatically (Fig. 16.6) using the multipronged strategy described in Table 16.2.

DEVELOPING CONSENSUS

Given the paucity of real evidence to achieve what we think of as safe patient care, and because there is an urgent need to act,

TABLE 16.1

EVIDENCE-BASED INTERVENTIONS FOR SAFE PATIENT CARE

- Appropriate use of prophylaxis to prevent venous thromboembolism
- Use of perioperative beta-blockers in appropriate patients to prevent perioperative morbidity and mortality
- Use of maximum sterile barriers while placing central intravenous catheters to prevent infections
- Asking that patients recall and restate what they have been told during the informed consent process
- Continuous aspiration of subglottic secretions to prevent ventilator-associated pneumonia
- Use of pressure-relieving bedding materials to prevent pressure ulcers
- Use of real-time ultrasound guidance during central line insertion to prevent complications
- Patient self-management for warfarin to achieve appropriate outpatient anticoagulation and prevent complications
- Appropriate provision of nutrition, with a particular emphasis on early enteral nutrition in critically ill and surgical patients
- Use of antibiotic-impregnated central venous catheters to prevent catheter-related infections

another strategy has been to develop consensus guidelines. Although such guidelines are not based on randomized trials, there is value in getting the best and most experienced minds together to synthesize what all would agree to be best practices. Trials may come later to support or refute consensus.

A very influential group that develops consensus guidelines is the National Quality Forum (NQF), an organization of a wide variety of experts, consumers, government officials, and corporate directors. The NQF several years ago published its list of “30 Safe Practices” recommended for implementation. Because this chapter is oriented toward surgery, Table 16.3 lists a selection of the 30 Safe Practices germane to the inpatient setting.

Consensus and Accreditation

The NQF works closely with the Joint Commission. When the NQF has reached consensus on a specific safety practice, this is often translated into a Joint Commission requirement for hospital accreditation, in this setting recognized as Joint Commission “patient safety goals.” These goals are more specific than consensus guidelines and have more “bite” to them, in that all hospitals need to fulfill these requirements in order to be

TABLE 16.2

UNIVERSITY OF MICHIGAN PROTOCOL FOR PREVENTION OF VENTILATOR-ACQUIRED PNEUMONIA (VAP)

- Hand washing/hand sanitizing
- Chlorhexidine oral rinse prior to intubation, then q12h on 0900–2100 schedule
- Oral care with swabs q2–3h
- Head of bed elevated 30–45 degrees on all patients at all times, unless medically contraindicated
- Extubate early—as soon as safely possible
- Turn off tube feedings when placing patients flat for turning or for procedures, unless small-bore feeding tube postpyloric
- Endotracheal tube tape changed every 48 h
- Minimal use of saline lavage
- Change ventilator tubing only when soiled
- Staff education and updates on VAP

FIGURE 16.6. Ventilator-associated pneumonia—University Hospital intensive care units.

accredited. For example, goal 7, “Reduce the risk of health care associated infections,” stipulates, among other things, that hospitals have specific strategies in place to prevent surgical site infections (SSIs); that they provide regular feedback about SSI rates to caregivers, with follow-up for 30 days; that they discontinue the use of shaving as a method of preoperative hair removal; and so on. Goal 8, “Reduce the risk of patient harm resulting from falls,” stipulates that each hospital implement a specific falls reduction program.

Consensus, Accreditation, and Payment

The Centers for Medicare and Medicaid Services (CMS) has a lot to say about implementation of safety practices in that they pay a large fraction of the nation’s health care bill. As it regards safety in surgery and hospital care, CMS has embarked on two important strategies. The first is the Surgical Care Improvement Project (SCIP), whose stated goal is to reduce the incidence of selected surgical complications 25% by the year 2010. To do this, CMS produced several specific process measures that are required to be met by hospitals before receiving full payment for services. Private insurers soon followed suit. SCIP measures are listed in Table 16.4. In contrast to the more broadly defined consensus guidelines, SCIP measures have a strong evidence base. Whether

this effort will be translated into national improvement in results remains to be determined. The Joint Commission has also integrated certain SCIP measures into its evaluation requirements.

Another important strategy embarked upon by the CMS is known as “nonpayment for hospital-acquired conditions,” otherwise referred to as the “never event” policy. In this strategy the CMS has determined that it will not reimburse for flagrant medical errors, such as wrong patient, wrong side, or wrong site surgery. Administrators and surgeons don’t object to this policy as far as it goes. But great concern has been raised about other conditions on the “never event” list, such as venous thromboembolism (VTE) or patient falls. The controversy arises because in these cases there does not exist an evidence base that would allow a hospital to eliminate these events entirely. Perfectly appropriate VTE prophylaxis, for example, only reduces the incidence of postoperative VTE by 50%. This situation seems unfair, and the list of “never event” conditions is progressively growing longer. Whether this strategy will really improve quality and make patients safer remains to be proven.

TABLE 16.3

NATIONAL QUALITY FORUM SAFE PRACTICES

- Create a culture of safety.
- Obtain explicit informed consent.
- ICU patients managed by critical care certified providers.
- Implement computerized physician order entry.
- Implement protocol for wrong side/site prevention.
- Evaluate for venous thromboembolism/implement prophylactic protocols.
- Develop facility-wide anticoagulation services.
- Adhere to effective measures for preventing bloodstream infections.
- Implement appropriate methods (antibiotic administration) for the prevention of surgical site infection.
- Evaluate each patient at admission for the risk of malnutrition.
- Develop effective hand sanitizing policies.

ICU, intensive care unit.

TABLE 16.4

SURGICAL CARE IMPROVEMENT PROGRAM (SCIP) PROCESS AND OUTCOME MEASURES

Infection (INF)

- SCIP INF 1: Prophylactic antibiotic received within 1 h prior to surgical incision
- SCIP INF 2: Prophylactic antibiotic selection for surgical patients
- SCIP INF 3: Prophylactic antibiotics discontinued within 24 h after surgery end time (48 h for cardiac patients)
- SCIP INF 4: Cardiac surgery patients with controlled 6 a.m. postoperative blood glucose
- SCIP INF 6: Surgery patients with appropriate hair removal.
- SCIP INF 7: Colorectal surgery patients with immediate postoperative normothermia

Venous Thromboembolism (VTE)

- SCIP VTE 1: Surgery patients with recommended venous thromboembolism prophylaxis ordered
- SCIP VTE 2: Surgery patients who received appropriate venous thromboembolism prophylaxis without 24 h prior to surgery to 24 h after surgery

TABLE 16.5**AGENCY FOR HEALTHCARE RESEARCH AND QUALITY
PATIENT SAFETY INDICATORS**

1. Hospital-level patient safety indicators
 - Complications of anesthesia
 - Death in low-mortality DRGs
 - Decubitus ulcer
 - Failure to rescue
 - Foreign body left in during procedure
 - Iatrogenic pneumothorax
 - Selected infections due to medical care
 - Postoperative hip fracture
 - Postoperative hemorrhage or hematoma
 - Postoperative physiologic and metabolic derangements
 - Postoperative respiratory failure
 - Postoperative pulmonary embolism or deep vein thrombosis
 - Postoperative sepsis
 - Postoperative wound dehiscence in abdominopelvic surgical patients
 - Accidental puncture and laceration
 - Transfusion reaction
 - Birth trauma—injury to neonate
 - Obstetric trauma—vaginal delivery with instrument
 - Obstetric trauma—vaginal delivery without instrument
 - Obstetric trauma—cesarean delivery
2. Area-level patient safety indicators
 - Foreign body left in during procedure
 - Iatrogenic pneumothorax
 - Selected infections due to medical care
 - Postoperative wound dehiscence in abdominopelvic surgical patients
 - Accidental puncture and laceration
 - Transfusion reaction
 - Postoperative hemorrhage or hematoma

DRGs, diagnosis-related groups.

PATIENT SAFETY INDICATORS

The AHRQ is another national group, funded by the National Institutes of Health. Several years ago the AHRQ developed 21 patient safety indicators (PSIs), which are thought to reflect on an institution's safety. These indicators are captured from a hospital's coding system, using International Classification of Diseases-9 (ICD-9) codes after patient discharge. The PSIs are listed in Table 16.5. While useful information can be obtained from this system, a disadvantage is that the data are obtained from medical billing coders, and may not accurately reflect whether a complication was actually preventable. An example might be the PSI labeled "accidental puncture and laceration." An enterotomy made during the course of a difficult dissection in an irradiated and multiply operated abdomen would fit into this category and be interpreted by nonsurgeons as an "accident." The surgeon who was carefully dissecting under these circumstances would definitely not agree. Despite such limitations, the AHRQ PSIs will be publicly reported as a safety indicator by the government next year, and already form the basis of certain proprietary safety indices, such as those put forth by HealthGrades.com or the University Health System Consortium.

EFFORTS FROM THE WORLD HEALTH ORGANIZATION

Recognizing that patient safety should be a global imperative, the WHO, working with the Joint Commission, has embarked on an ambitious project to reduce the incidence of medical errors internationally. One effort, known as the "high 5's" initiative, focuses on reducing five prevalent types of medical errors, over a 5-year period, in at least seven countries. The identified problem areas are (a) managing concentrated injectable medicines, (b) ensuring medication accuracy at transitions of care, (c) improved communication during patient care handovers, (d) improved hand hygiene, and (e) performance of the correct procedure at the correct body site.

The WHO has focused on surgical care specifically through a separate effort referred to as the "Safe Surgery Saves Lives" campaign. One very tangible result of this effort is the Surgical Safety Checklist, shown in Table 16.6.⁹ Now being tested in eight countries, the vision is that a standardized forum for intraoperative communication will be adopted internationally, much in the same way that the international aviation community has endorsed standardized flight checklists.

IMPLEMENTATION STRATEGIES

Establishing a safe culture is important, and emphasizing an evidence base and consensus guidelines is important, but ensuring implementation of what is known to be safe practice is critical and may be the most difficult of all safety strategies to accomplish. Several strategies have been helpful in our environment.

Adding Pharmacists to Rounds

Our medical center is a tertiary care referral center; the complexity of cases is high and always going higher. Transplants, complex oncologic problems, extracorporeal membrane oxygenation (ECMO) patients, and others with multisystem organ failure fill a large portion of our beds. The pharmacologic aspects of these cases are complex. Adding to the difficulty of managing such patients is the educational aspect of our enterprise, which guarantees a constant supply of new faces on rounds. To address these issues and to prevent errors, we have implemented a policy of adding a clinical pharmacist to each of our high-complexity services. The role of this individual is to suggest appropriate drugs, screen for allergies and incompatibilities, and monitor for important side effects. The program has been invaluable in improving patient safety at our institution and at others.¹⁰

Rapid Response Team

Mortality rates for in-hospital cardiac arrest have been high for decades, despite advances in cardiopulmonary resuscitation (CPR) techniques and cardiotropic medications. This is true particularly for "floor arrests," those cases of arrest occurring outside of the intensive care unit (ICU). In our center, and in many others, analysis of CPR cases has led to frustration that insufficient attention had been paid to the patient's condition in the hours prior to the arrest, at a time when interventions could conceivably have been very helpful.

One approach to this problem has been to develop a rapid response team (RRT), which is activated when certain physiologic parameters fall outside a specified range. Such parameters identified at our center are heart rate (<40 or >140 with new symptoms), respiratory rate (<8 or >36), blood pressure (systolic <80 or >220, diastolic >110 with symptoms), and unexplained change in cognition or neurologic status of adult inpatients. A key feature of the RRT activation is that it is seen as

TABLE 16.6**WORLD HEALTH ORGANIZATION SURGICAL SAFETY CHECKLIST**

BEFORE INDUCTION OF ANESTHESIA	BEFORE SKIN INCISION	BEFORE PATIENT LEAVE OPERATING ROOM
SIGN IN	TIME OUT	SIGN OUT
<ul style="list-style-type: none"> ■ Patient has confirmed: <ul style="list-style-type: none"> ■ Identity ■ Site ■ Procedure ■ Consent ■ Site marked/not applicable ■ Anesthesia safety check completed ■ Pulse oximeter on patient and functioning ■ Does patient have: <ul style="list-style-type: none"> ■ A known allergy? <ul style="list-style-type: none"> ■ No ■ Yes ■ Difficult airway/aspiration risk? <ul style="list-style-type: none"> ■ No ■ Yes ■ Risk of >500 mL blood loss (7 mL/kg in children)? <ul style="list-style-type: none"> ■ No ■ Yes, and adequate intravenous access and fluids planned 	<ul style="list-style-type: none"> ■ Confirm all team members have introduced themselves by name and role ■ Surgeon, anesthesia professional, and nurse verbally confirm <ul style="list-style-type: none"> ■ Patient ■ Site ■ Procedure ■ Anticipated critical events ■ Surgeon reviews: What are the critical or unexpected steps, operative duration, anticipated blood loss? ■ Anesthesia team reviews: Are there any patient-specific concerns? ■ Nursing team reviews: Has sterility (including indicator results) been confirmed? Are there equipment issues or any concerns? ■ Has antibiotic prophylaxis been given within the last 60 min? <ul style="list-style-type: none"> ■ Yes ■ Not applicable ■ Is essential imaging displayed? <ul style="list-style-type: none"> ■ Yes ■ Not applicable 	<ul style="list-style-type: none"> ■ Nurse verbally confirms with the team: <ul style="list-style-type: none"> ■ The name of the procedure recorded ■ That instrument, sponge, and needle counts are correct (or not applicable) ■ How the specimen is labeled (including patient name) ■ Whether there are any equipment problems to be addressed ■ Surgeon, anesthesia professional, and nurse review the key concerns for recovery and management of this patient

mandatory for nursing; no judgment is required. If the parameters are exceeded, the RRT is activated. This relieves some of the anxieties experienced by nurses in the past about communication with physicians, particularly at odd hours. In our center, activation of the RRT results in the timely arrival of an experienced surgical intensive care unit nurse and a respiratory therapist. If the conditions are found to warrant it, a hospitalist is called. This occurs in 15% of cases. There is controversy in the literature as to whether the RRT effort actually is effective.¹¹ However, the concept has so much face validity that most hospitals have accepted it as an important strategy to improve a safety culture.

An interesting, and entirely unexpected, offshoot of the RRT has been the process, by the RRT team, of visiting nursing floors on a shift-by-shift basis prior to any RRT activation. This process lets the team become more familiar with patients who might subsequently warrant RRT activation. Visits often foster a discussion among caregivers and family as to whether any intervention is appropriate or warranted.

Crew Resource Management

- 4 Another approach to the implementation of safe practices is to educate and train physicians and nurses within the context of a team. The team is defined, goals are set, and individual responsibilities are assigned. The completion of tasks (or omission) is apparent to members of the team, which provides a fail-safe structure. There has been considerable interest in crew resource management in the area of medicine since it has been conclusively shown to add value to aviation cockpit training. Crew resource management is probably best applied in small, well-defined areas, with relatively consistent staffing patterns, such as an operating room. In one report, a perioperative crew resource management training program consisted of an e-learning module, the develop-

ment of laminated checklists and pocket-sized cards, briefing scripts, a communication whiteboard, and a hands-on training program facilitated by experienced personnel. Even with focused effort at crew resource management, perioperative safety practice implementation was found to be less than perfect,¹² but the field, at least in medicine, is in its infancy, and it will probably be an important part of safety strategies in years to come.

Developing Collaborative Groups of Hospitals

Under conditions where motivated hospitals get together to discuss safety, the result is often a more consistent implementation of safety practices and better results. The development of a collaborative group directed at safety and/or quality allows for comparative evaluation of quality and safety, and often results in a spirit of friendly competition, which improves the aggregate level of safety.

A prominent example of such collaboration was mentioned previously, the Michigan Hospital Association-sponsored Keystone Initiative. Here, evidence-based practice for the care of patients in the ICU was monitored and found to be low across the state. A protocol was adopted for over 100 ICU groups, which included elevation of the head of the bed 30 degrees, ulcer prophylaxis, regular respiratory weaning trials, and a central line insertion protocol, with line maintenance involving chlorhexidine patches. When the latter protocol was implemented, a profound drop in the incidence of bloodstream infections across the state was seen, and the estimated cost savings exceeded \$160 million.⁶

In a different example, 34 Michigan hospitals formed the Michigan Surgical Quality Collaborative. These hospitals,

using the American College of Surgeons' National Surgical Quality Improvement Project (ACS NSQIP) as a quality reporting infrastructure, convene at 3-month intervals and share information about surgical results. Hospitals with the fewest complications in a specific area discuss why they feel they have been successful. "Best practices" are then distributed in a network including through the Internet, a hardcopy newsletter, and YouTube. Each hospital implements strategies it feels are appropriate for its situation. The result has been a sharp drop in the incidence of surgical complications. The results suggest that a collaborative quality organization, with regular and intensive sharing of data and best practices, is an essential vehicle for quality improvement.

PATIENT AND FAMILY INVOLVEMENT

One element of the patient safety movement that will become more important in the future is the involvement of the patient in various hospital safety strategies. A valuable source of information, and an important feedback mechanism, is lost when the patient, or family, is not a part of the care process. Two examples of the value of patient involvement involve hand washing and urgent care.

For hand washing, an effective hospital strategy prompts patients to ask physicians, "Have you washed your hands?" when they come into the patient's room. Physicians frequently wear buttons in this effort, which say, "Ask me if I've washed my hands." While it may seem trivial and somewhat demeaning to the physicians, the fact remains that the percentage of physicians and nurses washing their hands prior to patient contact remains far below 100%, and the prevalence of patient infection with *Clostridium difficile*, vancomycin-resistant *Enterococcus*, and other hospital-acquired infections remains high. In this context, patient involvement could be seen as a very important piece of Swiss cheese.

Another example of patient and family involvement in the care process is the concept of "family activation" of the rapid response team. Family members are often more aware of changes in a patient's condition than nurses or doctors, for the obvious reason that they know the personality and traits of the patient in detail. "He wouldn't complain about this unless it was really bad" is an important source of information from a wife. In the past, this clue to an evolving situation was sometimes lost on caregivers more focused on vital signs and urine output. In "family activation" of the rapid response team, family members are allowed to call a phone number activating the rapid response team if they feel that more attention is needed to a given situation. While it might seem that this would let loose a flood of such calls, in actuality, this has not been the case.

DEVELOPING A TAXONOMY FOR PATIENT SAFETY

Ultimately, comparative data on the safety of patient care in this country will be available to the public, much in the same way that the safety of retail products, medications, and automobiles is currently reported. For any reporting system to be valuable and fair, the definitions of safety events need to be refined and agreed upon. It is not possible to compare the safety of different hospitals if definitions used are not standardized. Many national organizations are working on this topic. The WHO has recently developed an "International Classification for Patient Safety" designed to "define, harmonize and group patient safety concepts into an internationally agreed upon classification in a way that is conducive to learning and improve patient

safety across systems." This work, while difficult, is essential for the patient safety movement.⁹

PUBLIC REPORTING OF SAFETY DATA

We live in an age of transparency. The public wants—and deserves—information about the safety record of a given hospital. And yet such information is hard to find. The future of the patient safety movement depends on the development of an effective safety reporting mechanism. This is because, in the absence of a large-scale database, information is not disseminated effectively, and one hospital may easily make the same mistake as its sister hospital down the street. One major impediment to the development of a national safety database is the lack of a standardized taxonomy of patient safety events. This problem is being addressed, as was just described.

Public reporting has been initiated using both voluntary and mandatory designs. Two examples of successful voluntary reporting systems are the National Nosocomial Infection Survey, a branch of the Centers for Disease Control and Prevention, and the MEDMARX program of the U.S. Pharmacopeia. Mandatory safety reporting systems are often state initiated and provide various sanctions for hospitals known to be engaged in unsafe practices. This penalty provides a disincentive to report, however. Only a few states have successful mandatory reporting systems.

One very successful example of a voluntary reporting system, albeit in the field of aviation, is the Aviation Safety Reporting System. This system analyzes 30,000 reports annually. Its success has depended on these factors: the system is simple, it is safe (for the reporting pilots), and it provides value.¹³ The patient safety movement would do well to emulate this system. When it does, and the taxonomy is standardized, doctors, nurses, and administrators will be considerably more willing to make safety data available to the public.

PART TWO

■ **SURGICAL PRACTICE**

CHAPTER 17 ■ TRAUMA AND TRAUMA CARE: GENERAL CONSIDERATIONS

RONALD V. MAIER

KEY POINTS

- 1 Injury is an epidemic in America, killing 150,000 and hospitalizing 3.0+ million while costing more than \$250 billion per year. Trauma is the leading cause of death to age 45 years, the fourth leading cause of death overall, and the leading contributor to years of potential life lost before age 65 overall. The major causes of injury-related death, in decreasing order, are motor vehicle crashes, penetrating trauma, falls, and burns.
- 2 Trauma deaths occur at three time periods following injury, each having a unique pattern and etiology: 50% at the scene, 30% within the “golden hour” or acute resuscitation phase, and 20% delayed from several days to several weeks after injury.
- 3 Modern trauma care is derived from the care of wounds and casualty management developed during major wars, and trauma systems are based on military experiences of improved survival in injured personnel produced by rapid transport to definitive care.
- 4 Trauma systems require a lead agency with designating authority, a formal verification process utilizing American College of Surgeons or similar standards, a limit on the number of centers based on patient needs, and triage criteria to deliver the right patient to the right hospital at the right time. The impediments of distance, discovery, training, and maintenance of expertise make rural trauma care a remaining major challenge.
- 5 Scoring systems allow objective quantification of the injury to assess impact on outcome and to track differences in outcome, both serially within an institution and between institutions and regional systems.
- 6 Traumatic injury results in deformation and structural damage of tissue dependent on the kinetic energy transferred to the host, which, in turn, is dependent on the mass and, to a much greater extent, the velocity of the injuring force. Varying mechanisms of injury produce predictable patterns of damage.
- 7 The interdisciplinary science of injury control requires a team approach that involves surgical and medical specialists, epidemiologists, statisticians, biomechanical engineers, public health practitioners, and economists.

EPIDEMIOLOGY

Injury has been a frequent cause of death in the United States since accurate statistics were first collected in the middle of the 19th century. With decreases in infectious diseases and the industrialization of society, injury has become a leading public health concern, which shows little sign of abating (Table 17.1).

- 1 In the United States, more than 3 million people are hospitalized annually as a result of unintentional injury, and approximately 35 to 40 million emergency department visits occur for the evaluation and treatment of injuries.¹ According to the most recent Centers for Disease Control and Prevention National Center for Injury Prevention and Control (CDC-NCIPC) statistics, 163,750 deaths resulted from injury in the United States in 2006 (Fig. 17.1).² Unintentional injuries account for about three fourths of these deaths (121,599 in 2006), and nearly one half of these were caused by motor vehicle crashes (MVCs), including occupant, pedestrian, and motorcyclist. Falls, occurring primarily among the elderly, are the second major cause of death from unintentional injuries. In 2002, there were 3,482 unintentional drownings and 14,050 burn injuries, with 2,670 deaths. Intentional injuries are responsible for just over 40,000 deaths per year, of which 66% are suicides and 34% homicides. Firearms account for 60% of all suicides and 72% of all homicides.³ Injury causes not only mortality but also significant morbidity. Each year, 37 million people are treated in emergency departments for injury and approximately 10% will require hospitalization.² It is estimated that the direct costs associated with fatal and nonfatal injuries total over \$60 billion per year.³ However, the overall impact of injury on society exceeds \$250 billion per year due

to years of lost productivity and chronic impairments. Of the 16 million people living with impairments in the United States, 44% cite injury as the cause of their disability.⁴ More than one half of all hospitalized trauma patients have fractures, dislocations, or ligamentous injuries. Orthopedic injuries are particularly problematic for the elderly.

Perhaps the single most responsible factor for the increase in the incidence of trauma has been the motor vehicle. Deaths from MVCs skyrocketed during the 1910s through 1920s, rising from an infrequent occurrence to a peak of 30 deaths per 100,000 per year during the 1930s and 1940s. During this time, trauma achieved its current status as the leading cause of death and disability among young Americans. Of these patients, more than 40% are between the ages of 25 and 44 years, and 20% are between 15 and 24 years. People under the age of 45 sustain almost 80% of all injuries and account for 75% of the total lifetime medical costs. Young males are the highest-risk group, not because of physiologic distinctions, but because of the propensity to engage in high-risk activities. According to data provided by the NCIPC, reported in 2001, considering all injury-related deaths (total of 157,070), 56.6% occurred in the age group of 15 to 49 years, predominantly in the male population.⁵ Overall, the risk of dying following injury for the male population is seven times higher than that for the female population.⁵ Trauma (intentional and unintentional injury) is currently the leading cause of death up to the age of 44 years and the fourth leading cause of death overall (after heart disease, cancer, and stroke).

Although morbidity and mortality figures are important, another important variable related to injury costs for society is measured in years of potential life lost (YPLL) before age 65. In the United States, these are the most productive for society⁶

TABLE 17.1**SIGNIFICANT HISTORICAL DEVELOPMENTS RELATED TO TRAUMA CARE**

■ PERIOD OR PERSON	■ CONTRIBUTION
Greek medicine	Wound care and fracture management
Roman Empire	Realization that laudable pus was undesirable Healing by second intention
16th century, Paré	Use of dressing and ligature in wound management
French and Indian War, John Hunter	Differentiation between primary and secondary wound healing
Early 1800s, Dominique Jean Larrey	Developed the principle of the ambulance and the concept of triage
Crimean War, 1853–1856	Demonstrated value of nursing care (Florence Nightingale)
Samuel Gross, 1862	Described shock as “the rude unhinging of the machinery of life”
Civil War	Rediscovery of importance of field ambulance, nonsuppurative wound care Initial use of antiseptics Further development of nursing care by Clara Barton, American Red Cross founder
World War I	Principle of débridement and delayed closure for wounds more than 8 h old Established primary closure for wounds <8 h old only Field ambulance mechanized with automobile availability Recognition that shock was due to blood or fluid loss and use of seawater to replace blood volume
World War II	Débridement and delayed closure practiced Diverting colostomies standard care for colon injuries Blood transfusion, rapid evacuation, specialized surgical units close to the front
Korean War	Development of Mobile Army Surgical Headquarters (MASH) units, use of helicopters, development of vascular surgery, field research leading to better understanding of posttraumatic renal failure
Vietnam War	Development of an airbase regional emergency medical system with transport from injury to intervention in 1 h or less Better fluid resuscitation to prevent renal failure Recognition of acute respiratory distress syndrome
Operation Enduring Freedom (OEF, Afghanistan) and Operation Iraqi Freedom (OIF)	More damage control operations, flying critical care air transport (CCAT) Optimal utilization of blood components: ratio of red blood cells to fresh frozen plasma to cryoprecipitate

and reflect the potential productivity that is lost as a result of premature death. As a result of its effect on younger age groups, traumatic deaths are the leading contributor to YPLL when compared with deaths associated with either cancer or cardiovascular diseases. In 1996, the age-adjusted YPLL before age 65 (per 100,000 population) was 1,919, 1,554, and 1,223 for injury, cancer, and heart diseases, respectively.¹ On average, for each traumatic death, there are 36 YPLL, compared with 16 for cancer and 12 for cardiovascular diseases.⁶

The leading causes of injury in decreasing rank include MVCs, firearms, falls, those related to cutting or piercing instruments, and burns. Fatalities after injury are mainly caused by MVCs (32%), gunshot wounds (22%), and falls (9%).⁷ Recently, in the rapidly growing elderly population, deaths due to falls eclipsed those due to MVCs.

Several important differences are found among the various ethnic groups in the United States in terms of the epidemiology of injury. The three leading causes of traumatic death for persons younger than 35 years are the same overall: MVCs, homicide, and suicide. However, in the African American population, the leading cause of death in this age group is homicide, whereas the mortality rate from MVCs is about 42 of 100,000 among Native Americans, 20 per 100,000 among the white population, and 11 per 100,000 in the Asian population.⁶ Similarly, suicide rates are higher for American Indians than for any other group.¹

The impact of injury in children younger than 15 is also significant. The leading causes of injury in this group are MVCs, burns, drowning, falls, and poisoning. Injury in this age group leads to a significant number of deaths, disabilities, days of missed school, medical costs, and missed workdays for parents. Adolescents are also at increased risk for injury. In fact, more adolescents die from injuries than from all other diseases combined (Fig. 17.1).⁸ Of all deaths in this age group, 40% are caused by intentional injuries, such as homicide and suicide.⁹ Considering only adolescents 15 to 19 years of age, one fourth of the deaths are caused by firearms.¹⁰

Alcohol ingestion is a major cause of fatal vehicular crashes. Although significant progress has been made in the prevention of drinking and driving, 32% of all traffic fatalities in 2007 were still alcohol related.¹¹ More importantly, 60% of the time that a child passenger dies in a car crash, the driver was intoxicated.¹¹ In addition, other commonly abused drugs, such as marijuana and cocaine, have been implicated in 18% of MVC-related fatalities.¹² Thus, those who participate in injury research and prevention must take into account both the unique characteristics of the specific target population and other important epidemiologic factors such as alcohol and drug use.

Although its position as the leading killer of young people has not changed, the overall mortality rate of trauma has gradually decreased during the past two decades. Prevention efforts

10 Leading Causes of Death, United States 2006, All Races, Both Sexes

Rank	Age Groups										
	<1	1-4	5-9	10-14	15-24	25-34	35-44	45-54	55-64	65+	All Ages

FIGURE 17.1. Ten leading causes of death, United States, 2006, all races, both sexes. (Data from the National Center for Injury Prevention and Control Department within the Centers for Disease Control and Prevention. 10 Leading Causes of Death, United States, 2006, All Races, Both Sexes. <http://webapp.cdc.gov/sasweb/ncipc/leadcaus10.html>.)

have been especially notable in the field of transportation safety. Fatal crashes decreased by 3.6% from 2006 to 2007, and the fatality rate dropped to 1.36 fatalities per 100 million vehicle miles of travel in 2006, the lowest since records began in the 1920s.¹³ Improved safety standards for vehicles, better roads, and a moderate decrease in alcohol-related crashes are the dominant contributing factors to this decline. However, some of the success in combating motor vehicle-related trauma has been offset by increases in death from intentional injury, principally that related to firearms. Deaths from firearms now outnumber those from traffic injuries in several states.¹⁴

MORTALITY PEAKS AFTER TRAUMA INJURY

- 2 Trauma deaths occur at three traditionally recognized times after injury (Fig. 17.2). Approximately half of all trauma-related deaths occur within seconds or minutes of injury and are related to lacerations of the aorta, heart, brainstem, brain, and spinal cord. Few of these patients are saved by health care systems, regardless of efficacy. In general, the only effective interventions for this primary peak in injury-induced mortality

are aggressive prevention strategies, either devices, such as automobile restraints and bicycle helmets, that prevent or lessen injury, or laws, such as drinking and driving penalties and motorcycle helmet laws, that limit certain risk-enhancing behavior patterns.¹⁵

The second mortality peak occurs within hours of injury and accounts for approximately 30% of deaths, about half of which result from hemorrhage and half from central nervous system (CNS) injuries. Important reductions in mortality rates during this period (“the golden hour”) have resulted from the development of trauma and emergency medical services (EMS) with rapid transport systems. Overall, preventable trauma mortality rates, as defined by expert panels, have been reduced from approximately 25% to 30% to 2% to 3% where well-organized trauma care systems exist.^{16,17} Currently, an estimated 85% of U.S. residents have potential access to level 1/2 trauma centers within 60 minutes,¹⁸ but for 28% this is by helicopter only. The nearly 50 million Americans who do not have access to organized trauma care within an hour live mostly in rural areas. Further development of trauma systems and evidence-based care protocols and expansion of these systems to rural areas will undoubtedly result in further reductions in mortality rates during this early postinjury period.

The third mortality peak includes deaths that occur from day 1 to 2 after trauma resuscitation and acute care to weeks

FIGURE 17.2. Three periods of peak mortality after injury.

later. This late mortality generally is attributed to infection and multiple organ failure (MOF).¹⁹ Of all trauma deaths, 10% to 20% occur during this period. The development of efficient evidence-based trauma care, however, is changing the epidemiology of these deaths. During the first week after trauma, refractory intracranial hypertension complicating severe traumatic brain injury (TBI) now accounts for a significant number of these deaths. The incidence of sepsis and MOF-related deaths following trauma has continued to diminish as a result of aggressive early resuscitation with improved goal-directed endpoints along with advanced organ support and ongoing critical care. Sepsis and MOF now account for approximately 5% of overall mortality and only 30% of later mortality where organized trauma systems and sophisticated intensive care unit (ICU) care exist. In addition to severe TBI, fatal pulmonary embolism also now accounts for a significant number of these late deaths.²⁰ Lastly, the aging of America has created an ever-increasing population of fragile elders with significant comorbidities, decreased organ reserve, and minimal ability to recover from the primary trauma insult. As a result, increasing challenges are the ethics of end-of-life and palliative care decision making. In the severely injured very elderly patient, just because “it can be done” does not necessarily justify that “it should be done.” From both unnecessary patient suffering and consumption of limited critical resources viewpoints, thoughtful, ethical, and appropriate intervention or lack of intervention must be applied.

Optimal efforts to reduce the morbidity and mortality of trauma must include specific programs for each of the three separate mortality peaks. Early deaths can best be reduced with injury prevention programs and educational outreach or legislated use of protective devices and control of dangerous behavior. Focus on the regional planning and fiscal support of trauma system development will affect the number of avoidable deaths during the second “golden hour” mortality peak. Finally, late deaths will be diminished as research generates better understanding of the extensive physiologic processes and cell biology related to inflammation, immune dysfunction, sepsis, coagulopathy, multiple organ failure, and CNS injury and development of proven evidence-based care.^{21,22}

which public health interests so closely overlap those of direct delivery of care. The most significant advances in the care of the injured patient that have occurred in the past 50 years are in surgery, anesthesia, imaging technology, and a better understanding of the basic cellular and genomic responses to shock and inflammation. But, in addition and unique to trauma care has been the coordinated societal effort at developing a trauma *system* of care, one that spans the continuum from injury occurrence, notification, and transportation to emergency and surgical interventions, critical care, rehabilitation, and eventual community reincorporation. These advances are highlighted both in the treatment of individual patients and in the establishment of effective systems of prehospital, hospital, and rehabilitative care. Trauma systems have become the paradigm for regionalized health care in the 21st century.²²

Over time, these trauma systems have become more inclusive, attempting to recruit all appropriate institutions and covering all levels of resources, to optimize access to care for all injured patients. The ideal system, however, must still be “selective” to avoid expensive duplication of resources resulting from excessive designation of frequently competing institutions that then exceeds the needs of the injured patient population. An approach of matching resources to patient population needs produces efficient utilization of expensive resources along with generation of high patient volumes and clinical experience, leading to improved patient outcomes while still being able to respond to the needs of each injured member of society. Such a functional system requires a lead authority, usually located in the state department of health, which is empowered to not only designate the appropriate number of institutions that meet the various levels of standards but also hold those institutions to appropriate standards. A triage plan is required that optimizes delivery of “the right patient to the right institution at the right time,” as dictated by the patient’s injuries. Further transfer guidelines allows near-seamless movement or transfer from hospital to hospital as dictated by patient need and availability of appropriate resources. Ongoing quality assurance (QA) or improvement (QI) derived from evidence-based medicine (EBM) assesses appropriate implementation of what is acknowledged as the correct approach in providing care to increase survival and decrease morbidity and long-term disability. While access to the system should be universal and is universally advocated, this has been a great, unresolved challenge, particularly in the vast rural areas of America and for an increasing number of underinsured and uninsured Americans everywhere. The development of this regionalization paradigm has been politically charged due to perceived loss of patients and potential

TRAUMA CARE AND TRAUMA SYSTEMS

Trauma care providers have an important role in combating the injury epidemic in the United States. Few areas exist in

revenue through triage and bypass of institutions to optimize patient care. And, most recently, the shortage of general surgeons and appropriate surgical specialists has created an enormous threat to maintenance of the system and patient access to care. Only with persistence and increasing societal, legislative, and financial support can these hurdles be overcome. Both active resistance and cultural inertia have led to significant delays in the full deployment of the trauma system. However, the quality of care, improvement in outcome, and recognized decrease in morbidity and disability strongly support and stimulate the need for ongoing system development so more and more states and regions have fully integrated trauma systems, accessible to every injured patient.²³

MILITARY HERITAGE AND DEVELOPMENT OF TRAUMA SYSTEMS

- 3 Our approach to modern trauma has grown primarily out of the care of wounds and casualty management resulting from war and recent increases in global terrorist attacks. Advances in rapid transport, volume resuscitation, wound management (both débridement and infection control), blood banking and appropriate utilization, enteric injury management, damage control concepts, vascular surgery, and surgical critical care and the need for early nutritional management have all come from or been significantly enhanced by military experiences. Salient historical events are shown in Table 17.1. Although by no means complete, this table provides examples of the many and significant contributions derived from extensive military experiences treating casualties with multiple injuries.

Care of the trauma patient poses several challenges not encountered in other aspects of surgical care. First, injury frequently occurs at a site remote from medical care. This problem couples with the importance of a time-critical injury requiring means for identifying and transporting critically injured patients quickly. Additionally, the polytrauma patient often requires complex surgical care that crosses specialty lines, requiring that an interdisciplinary team be available with little advanced planning or notification. The primacy of time renders an *ad hoc approach* to the delivery of trauma care unacceptable and is the principal impetus for the development of organized systems of trauma care.

It was the American experience in the Korean War that laid the earliest foundation for the current system of trauma care in the United States. The terrain made it difficult to evacuate the wounded along the traditional chain from the front lines to definitive care, as occurred during World War I and World War II.²⁴ Simultaneously, helicopters had evolved and were used to rapidly move the wounded from combat zones to mobile army surgical hospitals (MASHs). Additional experience with rapid evacuation to definitive surgical care was obtained during the Vietnam War, such that mean transport times dropped from 4 hours to 1.25 hours to 27 minutes in World War II, the Korean War, and the Vietnam War, respectively. Over these three conflicts, there was a concomitant reduction in mortality rates from 4.5% in World War II to 1.9% in the Vietnam War. It is likely that several factors contributed to the reduction in mortality over this interval; first among them was the military control of airspace that permitted the rapidity with which the injured soldier reached definitive medical care.²⁴ Most recently, the addition of flying critical care air transport for large numbers of critically ill casualties in B17 transports during Iraqi Enduring Freedom (IEF) has allowed transport to definitive optimal care facilities out of the war zone.

In Vietnam, the importance of rapid transport and a prepared receiving facility was well recognized. The distribution of trained personnel, equipment, and medical care was

designed such that no soldier in Vietnam was more than 35 minutes away from a medical facility capable of giving definitive, resuscitative lifesaving treatment.²⁴ This model of prehospital care became the framework and expectation for prehospital civilian care in the United States over the next several decades.

In 1966, coincident with the observations made in Vietnam, the National Academy of Science/National Research Council report on trauma explicitly stated that the quality of civilian trauma care in the United States was below the standard achieved in Vietnam, such that “Expert consultants returning from both Korea and Vietnam have publicly asserted that if seriously wounded, the chances of survival would be better in the zone of combat than on the average city street.”²⁵ In response to this report and in an attempt to improve trauma care delivery, the American College of Surgeons and its Committee on Trauma developed criteria for the designation of trauma centers and the establishment of regional trauma systems in 1976.²⁶

Civilian progress in trauma care, in general, has followed the evolution of military medical systems. In 1922, the importance of orthopedic trauma was first recognized in the United States with the establishment of the Committee on the Treatment of Fractures. This evolved into the Committee on Trauma of the American College of Surgeons in 1949. Increased awareness of traffic injuries and fatalities during the 1950s and 1960s began to raise surgical awareness and public concern leading to the opening of a dedicated trauma entity in 1961 at the University of Maryland, and the concept of the “golden hour” was established. In 1966, the National Academy of Sciences and the National Research Council’s important white paper, entitled *Accidental Death and Disability: The Neglected Disease of Modern Society*, increased public awareness and led to a federal agenda for the general improvement in trauma care.²⁵ Coupled with leadership from key academic centers and often by surgeons with recent military experience, the spread of advanced military concepts in trauma systems began. The Maryland Institute of Emergency Medicine became the first organized, statewide, regionalized system in 1973, while Harborview Medical Center in Seattle created the first fire department–based prehospital medical care delivery system for both acute cardiac and trauma events in 1969.²² Prehospital provider programs grew from these early attempts and were formalized, as emergency medical technicians (EMTs) and other paramedical personnel were identified, and training programs were established. In 1973, the Emergency Medical Service (EMS) Act became federal law, providing specific endorsement and financial assistance for the development of comprehensive prehospital emergency medical service systems. In addition to federal efforts, state and local legislatures began to organize strategies to care for injured patients by using prehospital care systems to stabilize and deliver patients to major hospitals where appropriate care could be given.

Two other factors influenced the development of regionalized systems of trauma care in the late 1970s. First, major teaching hospitals in large cities had become regional trauma centers by default because of their experience and involvement in the trauma care of indigent patients. While the original country hospital system proved nonviable fiscally in the 1960s in most major cities, with strong academic leadership, these centers were taken over as major training centers and were able to develop as models for regionalization of trauma care. Second, and of at least equal importance, the American College of Surgeons Committee on Trauma developed a task force to publish *Optimal Hospital Resources for the Care of the Seriously Injured* in 1976, thus establishing a standard for evaluation of care. The most current version was published in 2006 and is the most comprehensive to date.²⁶ It establishes criteria for prehospital and trauma care and emphasizes the importance of ongoing QA and QI to confirm optimal outcomes. In addition, the American College of Surgeons Committee on Trauma

TABLE 17.2

TRAUMA CENTER DESIGNATION LEVELS IN THE UNITED STATES

■ TRAUMA CENTER LEVELS	■ DESCRIPTION	■ ESTIMATED NUMBER
1	Typically located in large urban environments, major cities. Provides full spectrum of trauma care 24 h/d with 24-h availability of in-house surgeon. Acts as a community leader in trauma research, education, and prevention. Expected to admit >1,200 trauma, >20% of whom are severely injured.	190
2	In population-dense areas, supplements the resources of the level 1 center, whereas in more rural environments, may play the lead role in the community. Provides full spectrum of trauma care, 24 h/d. Surgeons must be rapidly available on short notice. Should coordinate outreach programs to incorporate smaller centers within the region.	263
3	Must have the capability to manage the initial care of most injured patients. General surgeon must be promptly available for major resuscitation. Will have transfer agreements in place to rapidly transfer patients to higher levels of care. Will have educational programs for physicians, nurses, and allied health care workers.	251
4/5	Provides initial evaluation and assessment of injured patients in rural and urban environments. Requires 24-h coverage by a physician (level 4 only). No specific requirement for surgeon or availability of specialists. Most injured patients will require transfer to larger facilities. Will have transfer agreements in place to rapidly transfer patients to higher levels of care as appropriate.	450

Washington, DC: Emergency Medical Services Resources and Disaster Readiness for Mass Casualty Events; 2003. Table from Nathens AB, Brunet FP, Maier RV. Development of trauma systems and effect on outcomes after injury. *Lancet* 2004;363:1794–1801, with permission from Elsevier.

developed the Advanced Trauma Life Support course in 1980, which has contributed greatly to uniformity in the initial evidence-based care of the injured and the development of a common language for diverse care providers.²⁷

TRAUMA SYSTEM COMPONENTS

Trauma centers are the core or “hub” of an organized system of trauma care. As originally conceived, the trauma center was an institution with all the resources necessary for immediate and definitive care of the critically injured patient. These centers, with their interested and committed staff, also served as the primary teaching sites for those interested in furthering their education in the care of the injured and performing the research to advance the evidence-based care of the injured. This description remains as the most consistent with a level 1 trauma center as an institution that takes a lead role for the provision of trauma care within a region. However, with an increasing understanding that it is neither desirable nor efficient that every injured patient must be transported to a center with all necessary resources available, a classification scheme for the designation of various levels of centers has evolved to allow a broad range of institutions to participate while still ensuring that standards are met to provide the appropriate level of care for the severity of injury (Table 17.2). This tiered approach improves the efficiency of trauma care by allowing higher-resource-level centers to focus on the more severely injured patient and reduces the likelihood that patients with minor injuries will be transported outside their community when they might best be cared for closer to home. Currently, more than 1,000 designated trauma centers exist in the United States, with just under half designated as level 1 or 2.²⁸

The trauma center represents the core of the trauma system; however, the system is much broader in scope. Specifically, mechanisms must be in place to ensure that severely injured patients are triaged and ultimately transported to a center where they can receive definitive care. If a patient is injured at a site remote from a level 1 center, agreements must

be in place to facilitate interfacility transfer from outlying centers. A QA program, both at the hospital level and at the system level, is critical to ensure optimal patient outcomes. Within a center, these QA programs allow for the evolution of evidence-based care protocols, whereas at the system level, they ensure adequate triage and the integrity of the triage and interfacility transfer process. These and other critical trauma system components were identified by West et al.²⁹ and then expanded by Bazzoli et al.³⁰ (Table 17.3)³⁰ Many have advocated that both injury prevention and postacute hospital care (e.g., rehabilitation) be included under the conceptual umbrella of the trauma system to better reflect the entire continuum needed for optimal trauma care.³¹

TABLE 17.3

ESSENTIAL TRAUMA SYSTEM COMPONENTS

- Presence of a lead agency with legal authority to designate trauma centers
- Use of a formal process for trauma center designation
- Use of American College of Surgeons (or similar) standards for trauma center verification
- Use of an out-of-area survey team for trauma center designation
- A mechanism to limit the number of designated trauma centers in a community based on community need
- Written triage criteria that form the basis for bypassing nondesignated centers
- Presence of ongoing monitoring systems for quality assurance (e.g., trauma registry)
- Statewide availability of trauma centers

From Nathens AB, Brunet FP, Maier RV. Development of trauma systems and effect on outcomes after injury. *Lancet* 2004;363:1794–1801, with permission from Elsevier.

The process of trauma center designation begins with a health regulatory agency–directed on-site verification of resources and commitment by either state health authorities or surveyors from the American College of Surgeons Committee on Trauma (ACSCOT) Verification Review Committee. Hospitals undergo verification at fixed intervals, consistent with either ACSCOT or regional regulatory requirements.

- 4 A lead agency with the legal authority to designate trauma centers is critical to the development of an organized system of trauma care. In many regions, the state or regional department of health holds this authority. This authority usually extends beyond the designation of trauma centers to encompass the development of criteria for the triage of patients and oversight of prehospital EMS care provided. Legal authority is critical because with the instatement of triage criteria, the potentially nearer, nondesignated centers are bypassed by EMS personnel in deference to a regional trauma center. In addition, the number, location, and level of centers must be based on population demographics (i.e., number of patients) and geography, rather than mere institutional interest, not only to ensure that the needs of the patients are met but also, importantly, to prevent unnecessary competitive duplication of expensive resources and optimize volume and experience in the trauma center. This process is apt to bring with it the fears of monopolistic business practices and resistance from the nondesignated centers. The identification of trauma centers in a region is perceived as a loss of market competition among the hospitals within that region, which might result in the loss of income for the nondesignated centers. Ensuring the system is backed by legislation helps to mitigate, but does not eliminate, these issues.

TRAUMA SYSTEM IMPLEMENTATION AND EFFECTIVENESS IN THE UNITED STATES

Progress in the implementation of organized systems of care in the United States has been difficult and is still limited in many areas. A major ongoing restraint is that the funding required to support the design, implementation, and maintenance of a well-integrated, coordinated regional system of trauma care is lacking. This is paradoxical in the face of the enhanced awareness and threat of terrorism, which virtually always involves mass casualties requiring the resources of the trauma care system. However, despite this chronic relatively limited funding, progress has been made; 38 states have implemented, or are in the process of implementing, organized systems of trauma care (Fig. 17.3).³²

Several lines of evidence suggest that an organized system of trauma care reduces mortality from injury. West and Trunkey³³ evaluated the preventable death rate caused by trauma in San Francisco County, California, where a single institution was responsible for all major trauma care, with the death rate in Orange County, California, where more than 40 centers managed trauma patients. In San Francisco County, only 1% of deaths were considered preventable, whereas almost three quarters of all deaths in Orange County were potentially salvageable. Subsequently, Orange County implemented a trauma system and demonstrated an eightfold reduction in the rate of preventable death as patients were triaged and cared for at designated trauma centers.³⁴ Population-based studies have also been used to evaluate the benefits of regional trauma centers. For example, Rutledge et al.³⁵ demonstrated that counties with designated trauma centers in North Carolina had a 20% reduction in per capita trauma deaths compared with counties without trauma centers, whereas Nathens et al.³⁶ demonstrated that states with an organized system of trauma care reduced MVC-related mortality by 10%. These results have been confirmed by MacKenzie et al. in the only prospective study analyzing

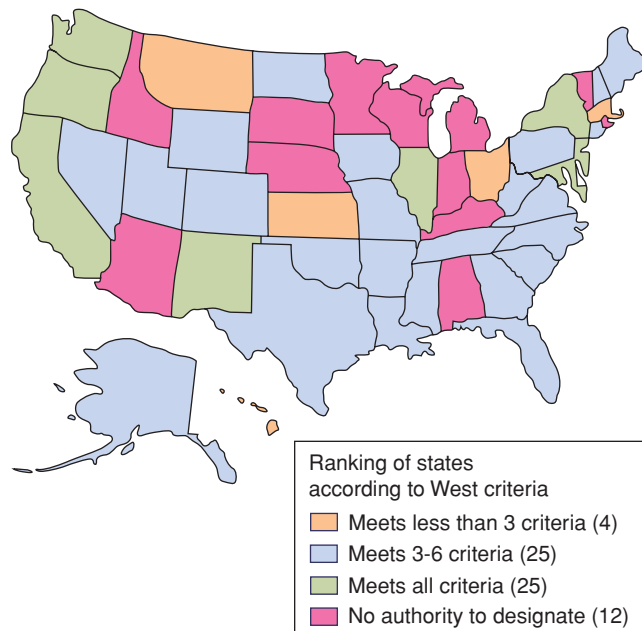

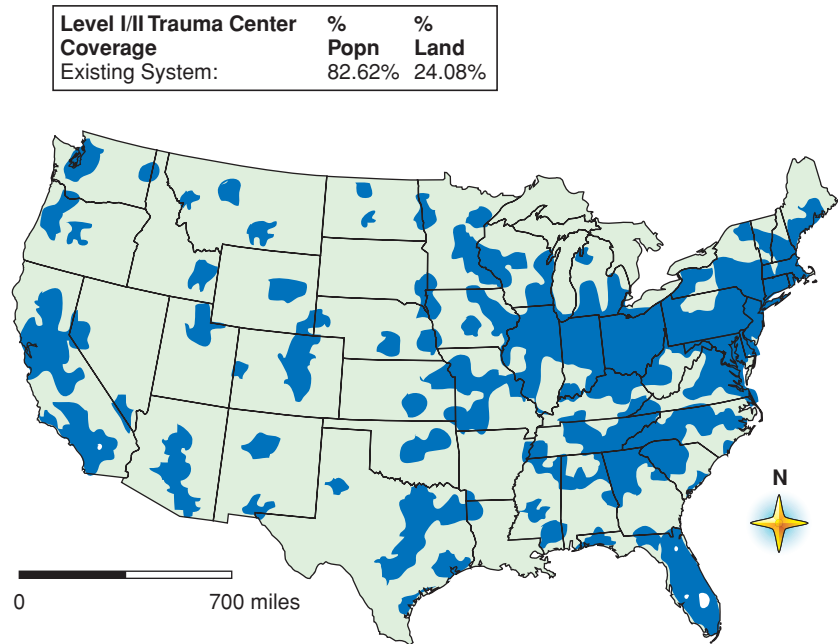

FIGURE 17.3. Regional trauma system in the United States as of 2002. States are ranked by the number of trauma system components implemented in their region. (From U.S. Department of Health and Human Services. *A 2002 National Assessment of State Trauma System Development, Emergency Medical Services Resources, and Disaster Readiness for Mass Casualty Events*. 2003. From <ftp://ftp.hrsa.gov/hrsa/trauma/nationalassessment.pdf>. Accessed November 2004.)

injured patients cared for in level 1 trauma centers versus community hospitals where a 25% reduction in mortality was shown.²³ However, these benefits are not achieved instantaneously, taking as long as a decade following enacting legislation to become manifest.^{37,38} It is likely that, after formal legislative implementation of the trauma system, a gradual change in care delivery and the process of quality improvement leads to better outcomes. Presumably, prehospital protocols improve such that the patients are more appropriately triaged to centers with adequate resources, whereas the trauma centers themselves evolve as they begin to commit an appropriate proportion of their resources to trauma and become more experienced due to increased volumes and thus capable of providing more optimal care.^{39–41}

RURAL TRAUMA SYSTEMS

Rural trauma care has been considered one of the great challenges in trauma system development.⁴² Approximately one third of the U.S. population resides in rural areas and account for those outside the “golden hour” for transport to a level 1 or 2 trauma facility, yet over half of all deaths caused by MVCs occur in the rural environment. To put this in greater perspective, the rate of death from MVCs is 600 times greater in rural Texas than in New York City.⁴³ Several factors play into this excess mortality. With a lower population density, discovery times, of necessity, are longer. Further, both EMS response times and transport times are longer; together, these factors increase the risk of prehospital death by as much as sevenfold.⁴⁴ In addition, prehospital personnel in rural environments are often volunteers with limited training. For example, in the rural state of Vermont, only 2% of all EMS providers are trained as paramedics capable of providing advanced life support (ALS).⁴² Many EMS providers in rural areas attend to fewer than 10 severely injured patients annually, making it virtually impossible for providers to maintain

FIGURE 17.4. Access to trauma centers in the United States. (From American Trauma Society. 2009 Maps of Trauma Center Access. <http://tramah.cml.upenn.edu/CML/TraumaCenters.Web/default.aspx>.)

an adequate level of experience despite adequate training. Similarly, physicians working in rural environments have limited exposure to the major trauma patient. Together, these data support the premise that enhanced training (with subsequent maintenance of skills), combined with mandatory time in the field, provides the best opportunity for optimal outcomes.

Given these impediments to providing adequate and timely trauma care, some rural states have implemented *inclusive trauma systems* such that virtually all hospitals are required to participate as designated trauma centers to the extent that their resources allow.⁴⁵ This approach is in contrast to *exclusive systems*, where most injured patients are transported to relatively few centers, which may be at great distance. Each region must decide the appropriate balances of patient needs and resources available. At a minimum, the structure of an inclusive system must ensure that the initial receiving hospital will have a plan as well as appropriate human material resources in place to provide initial, emergent management of the severely injured patient. In addition, once patients are assessed by the receiving center, they must be transferred as indicated to higher-level trauma centers for definitive care.

To facilitate this process, many hospitals (designated as level 3, 4, or 5 trauma centers) have interfacility transfer protocols and agreements with level 1 or level 2 centers to expedite the transfer process. In the rural settings, these lower-level trauma centers play a critical role in initial stabilization and triage.⁴⁶ Although conceptually sound, the efficacy of this approach is unproved. For example, when rural centers were designated in Oregon, evidence showed clearly that the distribution of trauma patients within the system changed; however, no significant measurable improvements in overall outcome were evident in this limited population of the most severely injured patients.^{47,48}

uniformly consistent across states and within regions. For example, the availability of trauma centers varies greatly across states, ranging from 0.9 to 6.6 centers per million population, and 25% of the land mass of America is not within 1 hour of a level 1 or 2 trauma center (Fig. 17.4).^{28,48} In addition, many of the states have not fulfilled many of the key components of trauma system design to ensure that populations within more sparsely populated regions have access to high-level trauma care (Fig. 17.3); thus, rural access to trauma care remains a major challenge in trauma system design.

SCORING SYSTEMS AND INJURY AND OUTCOME ASSESSMENTS

- 5 Many scoring systems have been developed in an effort to match injuries and trauma patients to allow comparison within and among institutions. Although all provide considerable help, none is perfect. The impetus for injury severity scoring systems is provided by the need to identify and classify severely injured patients in the prehospital phase, predict mortality, assess outcome results, and improve communication. Outcome analyses based on these parameters are a major objective of these types of scoring systems.⁵⁰ These systems also permit tracking of patient outcomes within an institution over time.

One simple way to classify trauma patients is to place them into three groups according to severity of injury: (a) those patients with injuries that are rapidly fatal, (b) those with injuries that are potentially fatal, and (c) those with injuries that are not fatal. The first group includes patients who have exsanguinating injuries, massive head injuries, high cervical spinal cord transection, or major airway disruption producing death in less than 10 minutes. Of traumatic injuries, 5% and half of all injury-related deaths fall within this category. The third group, which accounts for 80% of trauma patients, includes patients with injuries that are minor or confined to soft tissue and isolated extremity fractures. Significant risk to life is seldom seen in this group and urgent treatment is not essential. These patients survive without significant disability even if prolonged delays occur before definitive therapy. The real impact of improved prehospital care and organized trauma systems is on the second category of patients (15% to

SUMMARY

There is clear evidence that trauma system implementation reduces injury-related mortality.^{23,34-36} However, despite increasing trauma system implementation across the United States, approximately one third of major trauma victims are not cared for at regional trauma centers.⁴⁹ The reasons for this are multifactorial; however, it is likely that access is not

TABLE 17.4**REVISED TRAUMA SCORE COMPONENTS**

■ GLASGOW COMA SCALE	■ SYSTOLIC BLOOD PRESSURE (mm Hg)	■ RESPIRATORY RATE (Breaths/Min)	■ CODED VALUE
13–15	>89	10–29	4
9–12	76–89	>29	3

4–5	1–49	1–5	1
3	0	0	0

20% of the total): those who can be saved and morbidity minimized if effective medical care is provided quickly. It is for this group that trauma systems and scoring have been developed.⁴¹

Revised Trauma Score and Triage

The revised trauma score (RTS) developed by Champion and Sacco⁵⁰ in 1981 was for years the most widely applied scoring system for the initial evaluation of trauma victims. It mathematically combines the physiologic parameters of blood pressure, respiratory rate, and Glasgow Coma Scale Score to assess injury severity and predict which patients need the most timely and sophisticated medical care. Table 17.4 shows the components of the RTS.

While this mathematical model is uncommonly used today, the physiologic parameters included are still critical factors used to estimate injury severity and need for triage. In addition to physiologic scores, specific anatomic aspects of injury are also correlated with poor injury outcomes. Penetrating injuries to the head, neck, torso, and proximal extremities; multiple broken ribs and flail chest; two or more proximal long-bone fractures; pelvic fractures; limb paralysis; and amputation proximal to the wrist have all been identified as anatomic indicators of severe injury. Finally, the mechanism of injury is used to identify patients who are at high risk for significant injuries and are best evaluated at a trauma center. These data have been integrated with factors of age and comorbid disease into a triage decision scheme that is recommended by the American College of Surgeons and Centers for Disease Control and Prevention (Algorithm 17.1).

The major criticism of this triage scheme is that it leads to the frequent triage of patients to trauma centers that may not be necessary (i.e., overtriage). On the other hand, it diminishes the number of patients with severe injury who are overlooked and left potentially undertreated (undertriage). Overtriage is the inherent and necessary cost of a sufficiently sensitive scoring system. The exception to this approach is during disaster and mass casualty events when overtriage can consume limited resources and adversely impact overall patient outcomes and thus must be severely restricted.

Abbreviated Injury Scale

The Abbreviated Injury Scale (AIS)⁵¹ was developed in 1971 for use in blunt trauma and has subsequently been updated on a periodic basis. The 1990 revision of the AIS includes descriptors for penetrating trauma. Injury severity is determined in six different body areas on a scale of 0 to 6, where 0 indicates no injury, 5 indicates critical injury, and 6 indicates a nonsurvivable injury. The AIS evaluates individual injuries but does not account for multiple injuries. Thus, it is an injury-specific anatomic index.⁵² Table 17.5 shows an example of the AIS for abdominal injuries. The shortcoming of the AIS is that it eval-

uates each injury independently and recognizes only the most severe injury in each body area. Thus, AIS scores fail to account for multiple serious injuries within the same body compartment, thereby underscoring the true severity of the injury.

Injury Severity Score

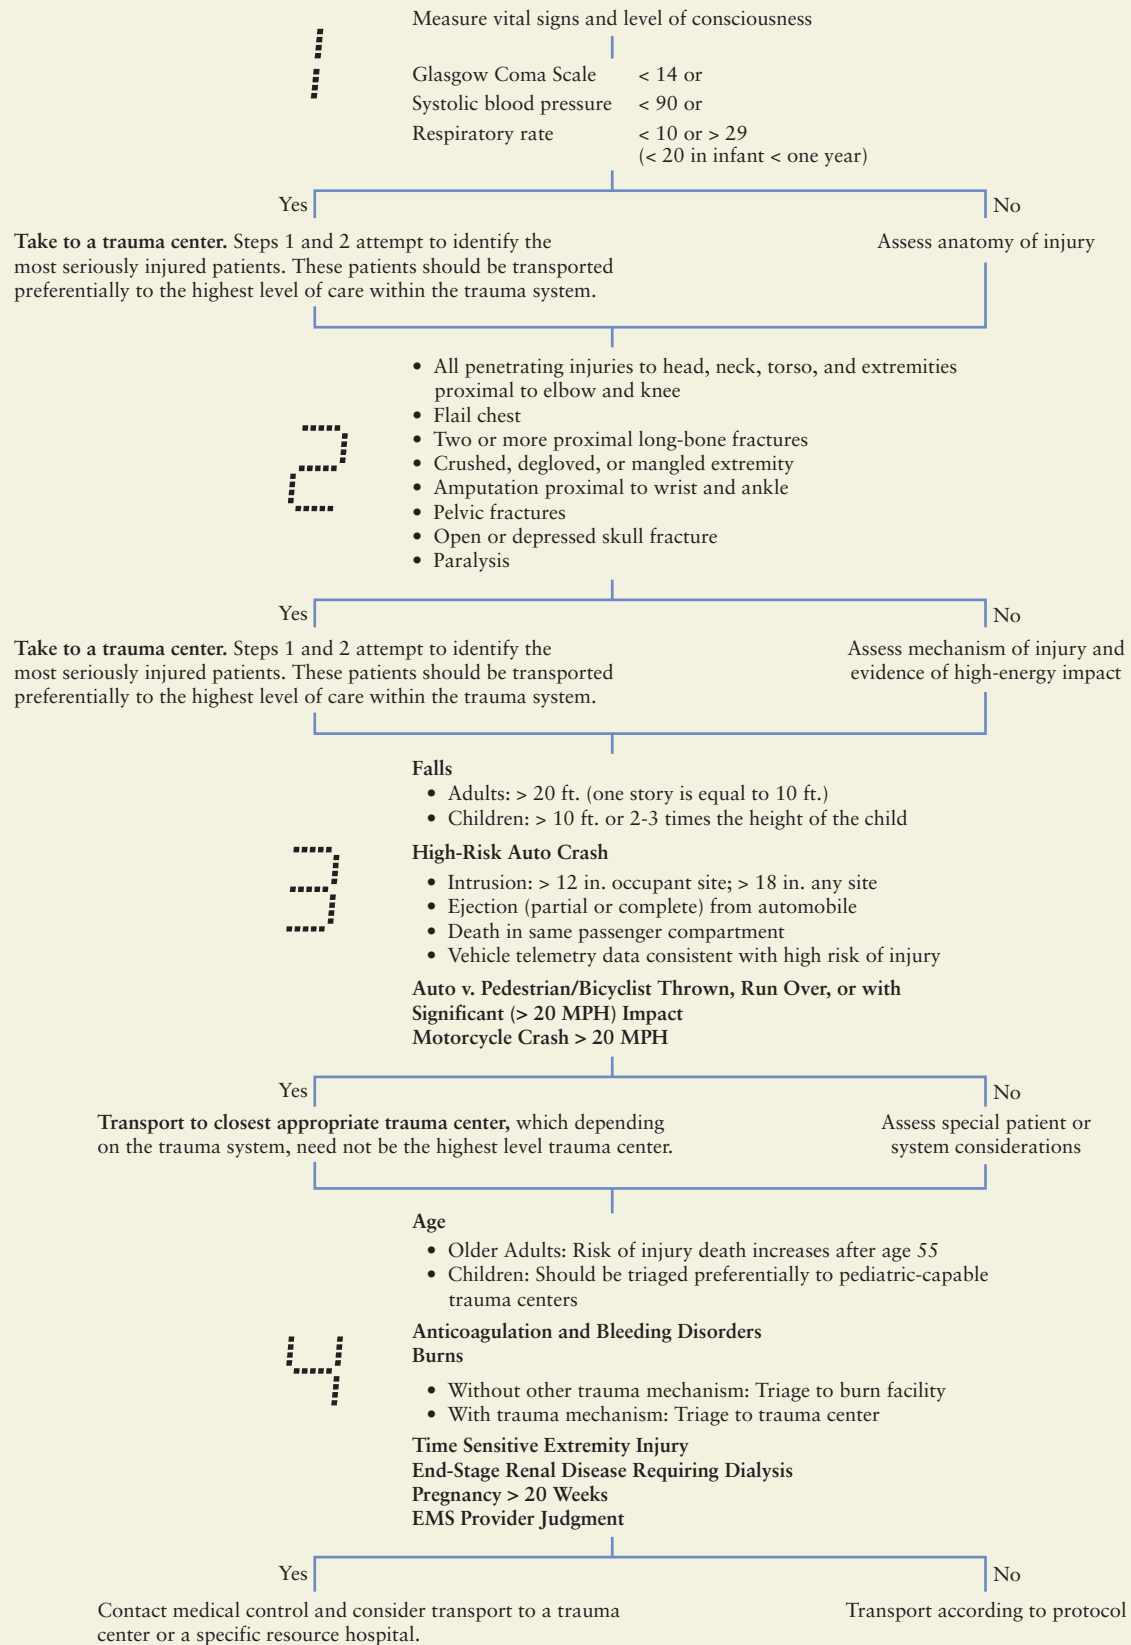

In 1974, Baker et al.⁵² developed the Injury Severity Score (ISS), which is calculated by assigning AIS values to the most severe injury in each of six body areas: head and neck (score = 1), face (= 2), chest (= 3), abdomen and pelvic contents (= 4), extremities and pelvis (= 5), and general and cutaneous (= 6). To derive the ISS, the scores for the three most severely injured areas are squared and added. ISS values vary from 0 to 75. If the value of the AIS is 6 (i.e., nonsurvivable injury) in any body area, the ISS is automatically 75.

The result is that substantial quadratic correlation between injury severity based on the ISS and death can be developed. The ISS is extremely helpful and has been widely used. However, it does not adjust for patient age or patient-related comorbid risk factors, such as chronic disease. Further, the severity of a head injury is disproportionately underscoring in that combinations of injuries in other areas can result in a higher ISS score than a fatal head injury. Despite these drawbacks, the ISS is an excellent tool for the study of groups of patients with multiple injuries from blunt trauma and allows comparison of outcomes and quality assurance. To address the concern of ignoring the impact of multiple injuries in one body region, a modified new ISS, or NISS, has been developed that includes the three most severe injuries, regardless of body region. Intuitively, this approach has advantages in patients with penetrating trauma where injuries are often concentrated in a single body region. In either blunt or penetrating trauma, this modification improves predictability and appears to better reflect and weight significant injuries than the ISS alone.⁵³

TABLE 17.5**ABBREVIATED INJURY SCALE SCORING SYSTEM FOR ABDOMINAL INJURIES**

■ SCORE	■ INJURY EXAMPLES
1	Abdominal wall abrasion
2	Liver, stomach, colon, mesentery contusion
3	Minor liver or spleen laceration Bowel laceration without perforation
4	Major liver or spleen laceration Bowel laceration with perforation
5	Major liver or spleen laceration with tissue loss Bowel laceration with tissue loss

FIELD TRIAGE DECISION SCHEME: THE NATIONAL TRAUMA TRIAGE PROTOCOL

ALGORITHM 17.1

Trauma and Injury Severity Score

The Trauma and Injury Severity Score (TRISS) methodology⁵⁴ is of importance because it attempts to combine the trauma score, or physiologic component of injury, and the ISS, or anatomic component of injury. It also incorporates the patient's age.

The TRISS method yields a specific probability of survival. Adjustments are made for age and mechanism of injury sustained (blunt or penetrating). The methodology allows patient groups to be compared. Individuals with an unexpected outcome, either survival or death, can be specifically identified and investigated. TRISS can be used for QI evaluations both within and between institutions. Typically, a cutoff point (e.g., predictability of survival, $Ps = 50\%$) is chosen, and records of the deaths of patients with a probability of survival greater than the cutoff value are submitted for peer review. TRISS also can be used to examine cases in which the survivors exceeded the cutoff value to help, in part, identify specific system components that improve outcome. In addition, TRISS can be used to compare trauma outcomes between different institutions or regions.

BIOMECHANICS OF INJURY

- 6 All traumatic injury occurs as a result of deformation of tissues beyond a threshold that results in structural damage. In general, injury is categorized as either penetrating or nonpenetrating (blunt) trauma or thermal injury. Blunt trauma injury is produced as the tissues are either compressed (crushed) or as deceleration (shear) occurs. In penetrating trauma, the injury is produced by crushing and separation of tissues along the path of the penetrating object.

Energy Transfer

The severity of any injury is directly proportional to the amount of kinetic energy transferred to the tissues, whether by a projectile or by blunt impact. Kinetic energy (KE) is a function of the mass (M) of an object and its velocity (V):

$$KE = (M \times V)/2$$

Changes in velocity alter the kinetic energy transfer more significantly than changes in mass. This fact becomes critical when assessing the extent of damage from high-velocity and low-velocity gunshot wounds. Likewise, a small child and a large adult, though significantly different in size and weight, are subjected to similar levels of energy transfer in a high-speed vehicular collision, the primary determinant being velocity rather than mass.

Cavitation

Cavitation occurs as tissue impacted by a moving body recoils from the point of impact, away from the object. The resulting transient tissue cavity can be caused by rapid acceleration or deceleration. Extreme strain occurs at points of anatomic fixation during the formation of these temporary cavities. Forces can be produced both along the longitudinal axis (tensile or compression strain) and across the transverse axis (shear strain). These types of forces cause deformity, tearing, and soft tissue failure or fracture. With penetrating trauma, transfer of kinetic energy from the projectile causes transient cavitation. A permanent cavity is produced by tissue displacement and destruction. Cavitation is the cause of tissue damage and loss beyond the immediate course of the projectile.

Biomechanics of Blunt Trauma

Blunt trauma results in two types of forces during impact. First, changes in speed (acceleration or deceleration) create shear strain, and second, deformity changes (stretch or compression) create tensile strain. For example, shear stress to the head secondary to deceleration leads to brainstem stretching, and injury to the spinal cord occurs from shear stress at points of attachment. Contrecoup brain injuries include stretch forces placed on bridging veins, which may lead to hemorrhage and a subdural hematoma.

Differential acceleration in the thorax makes the aorta the most common site of life-threatening shear injuries, the most frequent point of injury being the ligamentum arteriosum. Here, the descending aorta is tightly fixed to the thoracic spine, whereas more proximally it is relatively mobile. Shear stress in this area allows the proximal aorta to move forward in relation to the fixed distal aorta and, therefore, to tear. Abdominal injuries can result as a consequence of acceleration of the viscera at a rate out of proportion to movement of the points of attachment, in particular, vascular attachments. The kidneys, small intestine, large intestine, liver, and spleen are all vulnerable to this type of shear injury and vascular disruption. Similarly, with deceleration, the liver may continue to travel relative to the ligamentum teres, generating shear forces that transect or lacerate the hepatic parenchyma. An inappropriately applied, high-riding lap seatbelt, particularly in a small child, can also produce a shear plane across the edge of the belt, causing severe intestinal injury during crash-induced deceleration. Rapid deceleration can also place sudden flexion and extension forces on the spine with a seatbelt placed inappropriately high across the lower thoracic and upper lumbar spines, causing fractures, subluxation, or ligamentous injury (Chance fracture dislocation).

Tensile strain creates injury by directly compressing (crushing) or stretching the tissue. For the head, tensile strain results in fractures of the skull, which in turn may cause intracranial bleeding or contusions of the underlying brain parenchyma. In the thorax, external chest compression can lead to cardiac contusion, pulmonary contusion, pneumothorax, and fractured ribs or a flail chest. In the abdomen, the pancreas, liver, spleen, and occasionally kidneys are subject to tensile strain injuries, particularly following a frontal (or, for the kidney, flank) impact. In addition, direct compression of the abdomen may increase intra-abdominal pressure, rupturing the diaphragm. Similarly, external compression of the pelvis is associated with bladder rupture and other pelvic injuries.

MOTOR VEHICLE COLLISIONS

Specific patterns of injury are recognized for various types of motor vehicle collisions. These include (a) head-on or frontal impact, (b) rear impact, (c) lateral or side impact, (d) rotational impact, and (e) rollover. Some estimates of injury pattern are possible by analysis of damage to the vehicle, but the presumption should usually be that any or all of these forces may have been involved. In general, a vehicle's occupant receives a kinetic energy transfer similar to that of the vehicle itself. As an automobile collides with an object, passengers collide with the interior of the automobile, and the internal organs collide with the body wall or are sheared from anatomic attachments.

It has been shown that better automotive design has greatly improved the outcome for occupants when the safety features of the vehicle are in use at the time of the crash. Active safety restraint systems include shoulder and lap seatbelts, air bags (frontal and lateral), and door locks; passive restraint systems include front and rear energy-absorbing collapsible chassis, lateral bars, and improved lateral wall design.

FIGURE 17.5. Down-and-under (A) and up-and-over (B) mechanisms of injury after frontal deceleration impact.

Frontal and Rear Impact

With a frontal impact, the vehicle stops abruptly, and unrestrained front-seat occupants move in one of two predictable pathways: down and under the dashboard or up and over the dash or steering wheel (Fig. 17.5). With the former movement, the knees strike the dashboard and the upper legs absorb the primary energy transfer. Dislocated knees, fractured femurs, and posterior fracture dislocations of the hips are expected. With an up-and-over impact, the upper body flexes forward, moving up and over the steering wheel. The chest or abdomen impacts the steering wheel and the head impacts the windshield. The head stops the forward momentum of the torso and the cervical spine absorbs the kinetic energy. Predictable injury patterns resulting from the up-and-over component of a frontal impact are given in Table 17.6.

Rear-impact collisions occur when stationary objects or slow-moving vehicles are struck from behind. The amount of kinetic energy generated depends on the difference between the velocities of the two vehicles, rather than the sum, in forward collisions. After a rear impact, the vehicle and its occupants accelerate forward, during which time cervical spine hyperextension with possible injury may occur. If the vehicle slows to a stop spontaneously, often the occupants are not severely

TABLE 17.6

PREDICTABLE INJURY PATTERNS RESULTING FROM THE UP-AND-OVER COMPONENT OF FRONTAL IMPACT

- Rib fractures, pulmonary contusion, flail chest, and myocardial contusion from anterior chest-wall compression against the steering wheel
- Hollow abdominal viscera and solid organ compression, resulting in intestinal perforation and lacerations of the mesentery and solid organs, with accompanying hemorrhage
- After the anterior chest stops intrathoracic organs continue to move, resulting in shear injuries such as lacerations of the aorta or liver
- Shear injuries to the kidneys and other solid viscera
- Injury to the brain from direct compression with scalp lacerations, skull fractures, and cerebral contusions, or from deceleration and shear stress, which cause diffuse axonal injury and cerebral contusion or subdural hematoma
- Acute neck flexion, hyperextension, or both, causing a cervical spine injury

injured. If the car strikes another object, the occupants are thrown forward, with injury potential similar to that seen with a frontal impact. Thus, rear-impact collision can potentially cause two types of injury: those from the primary rear impact and those resulting from the secondary frontal impact.

Lateral and Rotational Impact and Rollover

Two patterns of injury result from lateral impact, depending on whether energy is transferred to the vehicle directly or imparts motion to the vehicle. If the target vehicle remains in place or there is significant passenger compartment intrusion, typical injuries include lateral crushing compression injuries to the torso, pelvis, and spine. Energy delivered to the chest with lateral compression can cause a flail chest, pulmonary contusion, and ruptured liver or spleen. Depending on the location of the occupant's arm, humeral and clavicular fractures may occur. The pelvis and femur are often impacted by the door, forcing the femoral head medially and causing an acetabular impaction fracture. Head injuries range from simple lacerations to cerebral contusions with intracranial hemorrhage.

When the vehicle does not move away from the point of lateral impact, an occupant who is restrained remains fixed in place and is more vulnerable to the intruding vehicle. More commonly, the force of the impact moves the vehicle, and passenger restraints markedly reduce injury. In this case, the occupant begins motion with the car and is pulled away from the impact point by the restraint. As the torso is pushed/pulled medially into the car, the head stays in its original position, producing lateral flexion and rotation to the cervical spine, which may lead to fractures and ligamentous injury. Passengers sustaining lateral impact also should be considered for injuries resulting from secondary collisions with other passengers and objects within the vehicle.

Rotational impact injuries occur when a car strikes a moving vehicle laterally. The moving vehicle rotates around the point of impact, resulting in a combination of the injuries seen in head-on and lateral impacts.

During rollover crashes, the automobile may impact many times from many different angles, and as a result, the occupant may have virtually any type of injury. All potential injury mechanisms should be considered. Rollover crashes with passenger ejection are associated with a profound increase in fatality rates (up to 10-fold), in part because the repeated second impacts can cause injuries that compound or exceed those resulting from the initial impact. Rollover crashes with passenger ejection are considered to have the greatest injury potential.

Restraint Device Injury

Theoretically, three-point passenger restraints, when used properly, allow the kinetic energy transferred by the impact to be absorbed by the bony pelvis and chest. If improperly positioned, however, lap belts may rise above the pelvis, delivering the compression force to the soft tissues of the abdominal cavity or retroperitoneum, and shoulder harnesses can enhance flexion and rotational stress on the cervical spine. The number of injuries related to restraint devices is increasing, reflecting the broader general use of these systems and increasing rate of high-speed collisions. While there is no question of the overall efficacy of these devices, the clinician must recognize possible specific restraint-related injuries.

Injuries caused by lap belts incorrectly strapped above the anterior iliac crest occur most frequently in small children. These include shear injury to intestines most commonly, compression injuries of the intra-abdominal organs (liver, pancreas, spleen, small bowel, large bowel), increased intra-abdominal pressure with diaphragmatic rupture, and anterior flexion compression and posterior distraction injury of the

lumbar spine. For these reasons and others, children shorter than 4 feet 9 inches tall, under 80 pounds, and younger than 8 years old should be placed in booster seats to allow appropriate positioning of seat belts. In addition, diagonal shoulder straps should be worn in combination with lap belts to prevent the forward motion of the trunk and excessive spine flexion. Diagonal shoulder straps should not be worn alone because this can be associated with chest and neck injuries if the pelvis is not also secured by the lap belt. Injuries associated with sliding underneath shoulder straps include carotid artery contusion, with or without thrombosis and disruption, and clavicle and rib fractures.

Air bags have enormous potential for injury prevention because they prevent the initial collision of passenger and automobile interior that occurs with frontal or lateral impacts. To be effective, air bags must be used in combination with seatbelts because they deflate immediately and therefore do not prevent secondary collisions. Lateral air bags are also increasingly incorporated in vehicles. Injuries such as lateral collisions of the head with the middle column and lateral compression of the chest wall and pelvis are in part prevented by these devices. Air bags are not effective in rear-impact collisions. However, given the predominance of frontal impact collisions, public health considerations by far favor that air bags should be strongly emphasized.

MOTORCYCLES

Motorcycle injuries involve four types of impacts: frontal, angular, ejection, and rear-end collision. In a frontal impact, the center of gravity is above and behind the front axle as the motorcycle tips forward and the rider travels over the handlebars. Injuries to the head, chest, or abdomen occur, depending on which part of the anatomy strikes the handlebars. If the rider's feet are placed on the pegs, the upper leg strikes the handlebars on forward motion, causing bilateral midshaft femur fractures. Angular or lateral impact from another vehicle or the ground when "laying the bike down" to avoid a collision generally results in crush injuries of the lower extremities. With ejection, the rider is thrown into the air until the head, chest, or extremities strike another object. Injury occurs at the point of impact, and, just as with the occupant ejected from the automobile, the potential for severe injury is high. This mechanism of injury is frequent and contributes importantly to the extraordinary injury potential for motorcycle riders.

In rear-end collisions, the motorcycle is usually at a stop when it is hit by a second vehicle from behind. The injury pattern is that of rapid acceleration with hyperextension and subsequent crush injuries on sudden stop.

PEDESTRIANS

Two general patterns are seen in motor vehicle versus pedestrian impacts, depending on whether the pedestrian is an adult or a child. In adults, the initial impact is often by the car bumper, producing fractures to the tibia and fibula. As the victim falls over the moving vehicle, the pelvis and upper femur are struck by the front of the vehicle's hood, and the abdomen and thorax continue onto the top of the hood. The secondary strike can result in fractures of the femur or pelvis and produce serious intra-abdominal or intrathoracic injury. Injury to the head depends on whether the patient's head strikes the car hood or is protected with the arms. A third impact occurs as the victim falls away, striking the ground. This impact commonly leads to head injury as well.

In children, the initial impact is predictably higher and may produce injury to the pelvis or upper femur. The second impact occurs when the front of the hood strikes the thorax. The final impact may not occur on top of the hood but rather as the

FIGURE 17.6. Hyperflexion and axial loading injury after a fall.

child is dragged underneath the vehicle. As the child falls backward, multiple impacts with the ground, underside of the vehicle, and wheels are possible, so virtually any type of injury may occur. Because of the potential for forceful impact and the direct blow to the middle torso, any child struck by a vehicle must be considered to have potentially severe crush injuries.

FALLS

Falls result in multiple impacts. Energy transfer is a result of the velocity that develops during the fall, so the height of the fall usually determines the magnitude of injury. Falls from more than three times the height of the victim, or from more than 20 feet, are considered severe. The surface on which the victim lands and its degree of compressibility (e.g., water vs. concrete) also have an effect on the energy transfer and the types of shear and tensile strain that occur. A typical injury pattern after falls in which the victim lands on his or her feet is transaxial and includes bilateral calcaneal fractures, lower extremity fractures, and multiple compression fractures of the thoracic and lumbar spine (Fig. 17.6). Of increasing importance are low-level falls (ground level falls [GLFs]) in the very elderly where the presence of significant comorbidities and medications (such as Coumadin) greatly enhance the risks of complications and mortality, even with relatively minor injuries.

GENERAL ANATOMIC CONSIDERATIONS IN BLUNT INJURY

The first and second ribs, sternum, scapula, and femur are considered to be some of the strongest and least vulnerable bones in the body. Therefore, fractures of these bones are indicators of severe trauma. Clear association exists between first and second rib fractures and injuries to the head, chest, and abdomen. Similarly, fractures to the sternum, though unusual, have a relatively high frequency of associated myocardial con-

TABLE 17.7

PATTERNS OF INJURY TO THE HEAD, NECK, TRUNK, AND EXTREMITIES ASSOCIATED WITH ORTHOPEDIC INJURIES

■ DIAGNOSED INJURY	■ ASSOCIATED INJURY
Fracture—temporal, parietal bone	Epidural hematoma
Maxillofacial fracture	Cervical spine fracture
Sternal fracture	Cardiac contusion
First and second rib fracture	Descending thoracic aorta, intra-abdominal bleeding
Fractured scapula	Pulmonary contusion
Fractured ribs 8–12, right	Lacerated liver
Fractured ribs 8–12, left	Lacerated spleen
Fractured pelvis	Ruptured bladder, urethral transection
Fractured humerus	Radial nerve injury
Supracondylar humerus fracture	Brachial artery injury
Distal radius fracture	Median nerve compression
Supracondylar femur fracture	Popliteal artery thrombosis
Anterior dislocation shoulder	Axillary nerve injury
Posterior dislocation of hip	Sciatic nerve injury
Posterior dislocation of knee	Popliteal artery thrombosis

tusion. Fractures to the scapula indicate significant thoracic trauma. A femur fracture in a frontal impact injury should raise the concern of acetabular fractures or dislocation of the knee. An inventory of specific orthopedic injuries and their commonly associated findings is provided in Table 17.7. These associations should be routinely considered during the initial evaluation following major blunt trauma.

The anatomic orientation of certain structures also leads to predictable injury patterns. For example, the right ventricle is the most anterior portion of the heart and therefore is the most commonly contused area. The association of splenic injury with rib fractures on the lower left side and liver injuries with rib fractures on the lower right side is also frequently seen after blunt trauma.

BIOMECHANICS OF PENETRATING INJURIES

Penetrating trauma involves the transfer of energy to a relatively small tissue area. The velocity of a gunshot wound is exceedingly high compared with any type of blunt trauma. The kinetic energy [$KE = (M \times V)/2$] of a bullet disrupts and fragments cells and tissues, moving them away from the path of the bullet. The actual size of the area of impact is determined by three factors: profile, tumble (spin and yaw), and fragmentation.

The profile, or frontal area, of a knife, screwdriver, or smooth bullet is that of a pointed missile. If the missile is crushed or deformed as a result of impact, the frontal area changes shape and disperses the impact over a wider tissue area, producing more rapid and greater energy exchange to the tissue and therefore greater injury. A knife or jacketed bullet does not

TABLE 17.8

MUZZLE VELOCITY, KINETIC WEIGHT OF PROJECTILE, AND APPROXIMATE MAXIMUM KINETIC ENERGY OF FREQUENTLY USED FIREARMS

DESCRIPTION (CALIBER)	PROJECTILE WEIGHT (g)	MUZZLE VELOCITY (ft/s)	KINETIC ENERGY (ft/lb)
Pistols			
.22 Short	29	1,000	72
.38 Special	158	870	263
9-mm Luger	125	1,150	440
.45	250	860	410
.357 Magnum	158	1,430	695
.44 Magnum	240	1,470	1,150
Rifles			
.22 Long	40	1,150	150
.56-mm M-16	55	3,200	1,248
.30-30 Winchester	170	2,200	1,830

deform significantly during impact, whereas a hollow-point bullet flattens, spreads, and fragments on impact.

Tumble results when the center of gravity of a bullet is eccentric, usually because it is located near the base rather than the apex of the bullet. Spin and axial movements (yaw) are bullet movements that occur after a gun is fired. At impact, spin and yaw continue to carry the base of the bullet forward, resulting in end-over-end motion or tumble. This increases the area and, thus, the amount of energy exchange and results in greater tissue damage. Multiple gunshot wounds are an example of the effect of fragmentation injury. The frontal impact damage can be estimated by classifying penetrating injuries into low-, medium-, and high-energy capacities.

Low-Energy Stab Wounds

Low-energy missiles include knives and other objects that produce damage by their sharp cutting edges. Cavitation is minimal and injury can be predicted simply by tracing the pathway of the weapon within the body. Knowledge of the type of weapon is sometimes helpful. Remember that the attacker may stab and move the knife or weapon inside the body, which can lead to more injury than that perceived from the cutaneous wound. Importantly, the ability to estimate the potential scope of injury by examination of the entrance wound is not reliable for stab or gunshot wounds.

Low- and Medium-Energy Gunshot Wounds

Low-energy gunshot wounds are defined as those with an initial muzzle velocity of less than 1,200 ft/s. Medium-velocity projectiles have muzzle velocities between 1,200 and 2,000 ft/s. Most handguns and some rifles are low- or medium-energy weapons. Table 17.8 provides a comparison of bullets and initial muzzle velocities for firearms frequently associated with penetrating civilian trauma. The primary point is that these weapons both damage the tissue directly in the path of the missile and produce cavitation injury to tissues in close proximity to the path. The size of the cavitation injury is directly proportional to the velocity of the bullet. However, the extent of tum-

ble, fragmentation, and profile change in the projectile also influence the amount of injury.

High-Energy Weapons

The essential difference between high-energy weapon wounds and the typical civilian gunshot wounds is that their projectiles produce a much larger cavity or pressure cone than low- and medium-velocity missiles. The temporary cavity extends well beyond the actual bullet tract, producing a wider injury. The vacuum created by the cavitation pulls clothing, bacteria, and other debris from the surrounding areas into the wound, creating the additional risk of contamination. The proliferation of semiautomatic weapons also has resulted in an increased number of wounds a victim may experience. Instead of a single gunshot wound, the surgeon may be faced with multiple wounds in multiple body locations.

Shotgun Injuries

Blast injuries caused by close-range shotgun fire (10 to 15 ft.) constitute devastating injuries composed of extensive tissue destruction. Besides specific organ injury, blast injuries due to wadding from the shell and extensive foreign body contamination have the highest potential for secondary infection. These injuries, in general, should be surgically explored, devitalized tissue should be extensively débrided, and the wounds should be left open and packed with sterile dressing that should be changed; the wounds should be reviewed serially for additional débridement in the operating room.⁵⁷

GENERAL ANATOMIC CONSIDERATIONS OF PENETRATING INJURIES

Evaluation of each entrance and exit wound helps to assess but does not confirm the number of projectiles, their courses, and which organs are at risk of injury. Close-range entrance

wounds for bullets typically cause tattooing, burning, and abrasion as a result of the spin. Depending on the range, there may be direct burning of skin. Tattooing occurs if the muzzle is within 12 inches of the skin at the time of firing. The range from which a gun is fired is also significant in that the air resistance that slows bullet velocity and reduces kinetic energy is proportional to the distance traveled.

Once a missile penetrates tissue, the energy is distributed predictably within a closed space, and, depending on the organs impacted and the types of tissue traversed, certain injuries can be anticipated. For example, a bullet penetrating

the skull may have insufficient residual energy to traverse and exit the opposite side of the skull. Instead, it may follow the curvature of the interior of the skull, generating a more severe brain injury than would result from a simple linear passage.

In the thorax, lung parenchyma has low mass and, therefore, sustains less damage from penetrating injury than any other thoracic tissue. Similarly, blood vessels that are not fixed may be pushed aside without significant damage. However, injury to adjacent blood vessels in proximity can result in intimal damage with subsequent thrombosis even if the vessel as a whole remains intact. Large fixed vessels such as the aorta and

FIGURE 17.7. Axial traverse (A) and transdiaphragmatic (B) wounding mechanisms with associated injury potential for combined thoracic and abdominal injuries.

TABLE 17.9**INJURIES ASSOCIATED WITH SPECIFIC VASCULAR TRAUMA**

- Superior mesenteric artery or superior mesenteric vein injury with pancreas and liver
- Renal artery injury with liver, kidney, and colon
- Inferior vena cava injury with liver, small bowel, colon, pancreas, and duodenum
- Axillary artery injury with brachial plexus trauma

vena cava are particularly susceptible to fatal injury. If bones are penetrated, bone fragments may become secondary missiles and can lacerate the surrounding tissues, including vascular structures. Muscles may expand out of the path of a missile, but this can result in vascular stretching and hemorrhage. Lower-velocity bullets may not follow a straight path but rather ricochet through the body cavity or track along fascial planes, injuring other organs.

Penetrating injuries should also be evaluated with regard to topography for potential anatomically associated proximity injuries. For example, penetrating wounds of the neck are commonly associated with injury to the jugular veins, trachea, pharynx, and carotid artery. Injuries to the trachea are commonly associated with injuries to the esophagus, and injuries to the carotid artery are commonly associated with internal jugular vein injury. In penetrating wounds to the thorax, possibilities of injury to the heart, lung, and diaphragm should be considered (Fig. 17.7A). The anterior location of the right ventricle makes it particularly vulnerable to penetrating trauma. All penetrating wounds below the nipple line or inframammary groove must be considered for potential intra-abdominal injury due to elevation of the diaphragm during expiration. Similarly, wounds that cross the midline, so-called transaxial wounds, are important to recognize (Fig. 17.7B). In the thorax, this indicates that every mediastinal structure is at risk, and in the abdomen, the possibility of major vascular injury, particularly to the aorta and vena cava, should be considered. Associated abdominal injuries often include hepatic and splenic injuries, as well as diaphragmatic, pulmonary, and gastric injuries. Duodenal and pancreatic injuries are commonly seen with injuries to the liver, inferior vena cava, stomach, and colon. Examples of injuries associated with specific vascular trauma are listed in Table 17.9. In all, gunshot wound penetration of the abdomen has associated injuries requiring surgical repair in 60% to 80% of patients.

THE ONGOING CHALLENGE OF TRAUMA

Spurred by two sentinel publications by the National Academy of Sciences and the National Research Council (NAS/NRC), injury has become recognized as a public health problem that has a greater impact on the United States than cancer or cardiovascular disease. In 1966, the NAS/NRC published a white paper entitled *Accidental Death and Disability: The Neglected Disease of Modern Society*.²⁵ Many have identified this publication as the inaugural event of what has become a sustained effort sponsored by the U.S. government to control unintentional injury and the injury epidemic. A 20-year follow-up study, entitled *Injury in America: A Continuing Public Health Problem*, appeared in 1985, outlining further efforts that would be needed to address the persistent problem of injury and the injury epi-

demic. The most recent contribution of the NRC Institute of Medicine (IOM) is the three-part series by the Committee on the Future of Emergency Care in the United States, including (a) *Hospital-Based Emergency Care: At the Breaking Point*, which describes the changing role of the hospital emergency department and the epidemic of overcrowding, uncompensated care, lack of availability of surgical specialists, liability exposure, lack of hospital disaster preparedness, and insufficient support for trauma research⁵⁸; (b) *Emergency Medical Services at the Crossroads*, which describes the fragmented EMS system, inadequate communication systems, lack of coordinated regional patient flow, insufficient reimbursement, lack of national training standards, lack of integration into disaster preparedness, and absence of clinical evidence to support care protocols⁵⁹; and (c) *Emergency Care for Children: Growing Pains*, which explains the 20 years of progress of EMS for Children (EMS-C) and the impacts of EMS magnified on EMS-C including training, readiness, medication issues, disaster preparedness, and research.⁶⁰ These excellent reviews identify the multiple ongoing stresses that have kept emergency and trauma care from achieving the goals necessary to optimally impact the epidemic of injury in America. Over the past four decades and especially since the development of the NCIPC at the Centers for Disease Control and Prevention, the health care community has been encouraged to assume, and has assumed, an enlarged role in injury control. Medical and surgical specialists, epidemiologists, statisticians, biomechanical engineers, public health practitioners, and economists are continuing to create the collaborations necessary to develop and implement the required sophisticated interdisciplinary approaches necessary for optimal injury control.

CHAPTER 18 ■ PREHOSPITAL AND RESUSCITATION CARE

EILEEN M. BULGER

KEY POINTS

- 1 Emergency medical service systems provide a rapid, tiered response to the injured, beginning with an Emergency Medical Technician-Basic (first responder) and followed by an Emergency Medical Technician-Paramedic, as needed.
- 2 Duration at the scene should be individualized to the patient's injuries and physiologic status. "Scoop and run" versus "stay and play" approaches cannot be generalized.
- 3 Airway control is paramount and, if required, should be achieved using an orotracheal approach with neck immobilization and neuromuscular blockade, if needed.
- 4 A multidisciplinary team of specialists, led by the "captain of the ship," usually a trauma surgeon, is available in level 1 and 2 trauma centers to provide coordinated optimal care for any and all injuries.
- 5 Trauma assessment and care are provided in a logical, consistent manner. The primary survey identifies and simultaneously treats life-threatening injuries, including airway loss, inadequate ventilation, ongoing hemorrhage, and central nervous system damage. The secondary survey identifies all other injuries, including those with potential long-term disability.

Care of the injured patient begins in the prehospital setting with a tightly integrated multidisciplinary emergency medical service (EMS) system. The goal of the EMS system is to provide immediate access to lifesaving medical care. This care usually entails the use of a first-response team, such as the fire department or other public safety personnel with the capability of providing basic life support (BLS) within minutes of an injury. When available, a rapid transport team capable of providing advanced life support (ALS) moves the injured patient to a trauma center where a multidisciplinary team meets the patient to continue resuscitation, identify injuries, and provide expeditious therapy, with the aim of completing all of these processes within 1 hour (called the *golden hour*). The goal of the EMS system is to assess for life-threatening injuries, initiate emergency care, and transport the injured patient as expeditiously and safely as possible to the nearest appropriate trauma center.

PREHOSPITAL CARE

Personnel

- 1 The initial goal of any EMS system is to provide a rapid response by personnel trained in BLS skills to the scene of the injured patient. In most cases, this function is performed by an Emergency Medical Technician-Basic (EMT-B). The EMT-B's responsibility is to assess rapidly the patient's airway, breathing, and circulation and look for evidence of obvious external hemorrhage. The EMT-B's skills include extrication, spinal protection, immobilization, splinting, and control of external hemorrhage. In most EMS systems, BLS is followed by ALS. ALS personnel are usually Emergency Medical Technician-Paramedic (EMT-P) or specially trained nurses or physicians and may have air or ground transportation capabilities. ALS personnel are trained in a variety of advanced skills including endotracheal intubation, intravenous (IV) access and drug administration, needle and/or surgical cricothyrotomy, and needle thoracentesis. However, significant variability exists

among different ALS systems regarding the procedures permitted and medications allowed for use by an EMT-P.^{1,2}

- 2 An area of frequent controversy in the literature involves the philosophy of rapid transport ("scoop and run") versus field stabilization ("stay and play") for the injured patient.³ The choice of approach for the individual patient often requires complex judgments. Decisions made by experienced on-scene EMTs, communicating online with trauma center control that will receive the patient, provide the best patient outcome.^{4,5} The procedures performed and the time invested depend on factors such as the patient's hemodynamic stability, level of consciousness, complexity of extrication, distance from the receiving trauma center, and experience of the prehospital personnel. Injured patients who are at risk for progressive deterioration from continued hemorrhage are better served with stabilization procedures done en route rather than at the scene.⁴

Nationally standardized training programs for EMTs, both BLS and ALS, have become popular. These programs, Basic Trauma Life Support (BTLS) and Prehospital Trauma Life Support (PHTLS), provide EMS personnel a curriculum to assist in making these complex decisions.

Assessment and Management Priorities

- 3 **Airway Assessment.** Because the most immediately life-threatening problem to the injured patient is loss of airway patency, this is the first priority of the first-response team on arrival at the injury site. Patients who are awake, alert, and talking obviously have a patent airway, but those who are unconscious or have evidence of respiratory insufficiency require immediate attention. Typical BTLS skills, such as suctioning, chin lift or jaw thrust, the placement of oropharyngeal airways, and the use of bag mask devices, are usually sufficient, at least temporarily, to restore oxygenation. On arrival of ALS personnel, a more definitive airway can be secured by endotracheal intubation. Endotracheal intubation is the best procedure for airway control for patients who are in shock, have abnormal breathing patterns, or are unable to protect the

airway because they are unconscious. Endotracheal intubation is a skill that requires proper training and regular use of the technique. In addition, ongoing quality assurance and continuing education are needed to maintain skills over time.

Training of paramedical personnel almost always includes endotracheal intubation, but the indications for intubation vary. The indications for intubation are often dependent on whether ALS providers are allowed to use neuromuscular blocking agents (NMBAs), such as succinylcholine, to facilitate intubation. In systems that do not have clearance to use NMBAs, intubation is limited to severely injured patients without airway reflexes. The use of NMBAs has been associated with increased success at achieving prehospital intubation with minimal complication rates.^{6–12} However, the absolute benefit of prehospital intubation for patients with traumatic brain injury remains controversial. Concerns have been raised that transient hypoxia associated with intubation or inadvertent hyperventilation after intubation could worsen outcome for these patients.^{13,14} In contrast, early intubation reduces the risk of gastric aspiration, which can be exacerbated by positive-pressure ventilatory assistance by bag valve mask and cause gastric distention.

Common indications for endotracheal intubation in the field include respiratory distress, unconsciousness, hypovolemic shock, significant head injury, severe chest injury, and facial burns. More liberal indications for endotracheal intubation include all patients with significant mechanism of injury and unstable vital signs or altered mental status. Intubation in an uncontrolled environment such as the prehospital setting can be difficult. Patients with head injuries are at high risk for cervical spine injuries, so in-line mobilization techniques are necessary. In patients in whom intubation is not successful, the use of a pharyngeal lumen airway or Combitube may be an option.¹⁵ Nasotracheal intubation is an effective technique if practiced frequently, but requires patient-initiated airflow to open the glottis; most paramedical personnel lack training in this technique, and patients with potential basilar skull fracture are not candidates for this approach. In some cases, needle or surgical cricothyroidotomy in the field may be the only way to establish an airway. Reasonable results have been obtained in the prehospital setting using cricothyroidotomy, but as with endotracheal intubation, mastering this skill requires ongoing training.^{16,17}

A recent expert panel, convened by the Brain Trauma Foundation, emphasized the importance of several system factors in the implementation of a prehospital Rapid Sequence Intubation (RSI) program.¹⁸ These include strong medical direction and oversight, protocol development, an implementation plan that includes both cognitive and technical training, appropriate prehospital triage, skill maintenance, and performance improvement. Furthermore, they note that “competent” performance of RSI is not limited to successful tube placement but also includes avoiding desaturations during RSI as well as subsequent hyperventilation, both of which have been associated with impaired outcome for patients with severe traumatic brain injury.

Breathing. After establishment of a patent and controlled airway, the next priority is to ensure that air exchange is taking place. Immediately life-threatening injuries that preclude air exchange include tension pneumothorax, massive open chest wounds, sucking chest wounds, and tracheal disruption. There are no maneuvers likely to correct tracheal disruption in the field. Both open chest wounds and sucking chest wounds respond to endotracheal intubation and positive-pressure ventilation. Tension pneumothorax occasionally requires field decompression. Field techniques to deal with tension pneumothorax include needle thoracostomy and chest tube thoracostomy in the midclavicular line of the second intercostal space. A recent review of prehospital needle thoracostomy suggested this was a relatively safe procedure but should be

reserved for patients with physiologic signs consistent with tension pneumothorax.¹⁹ Some trauma systems allow paramedical personnel to place chest tubes in the field or en route under medical control.²⁰ Chest tube placement probably is not necessary in urban trauma systems with short response times but may be of value in rural areas.

In addition to addressing mechanical factors that impair ventilation, such as tension pneumothorax, recent evidence has also suggested that we need to pay greater attention to the ventilation rate we provide the patient once the airway has been established.^{21,22} This is particularly important for a patient who may have a traumatic brain injury (TBI). Historically, hyperventilation was used routinely in the management of patients with severe TBI as a means to decrease intracranial pressure; however, this was abandoned once the effects on cerebral blood flow were evident. In 1991, a randomized controlled trial of prolonged hyperventilation versus conventional ventilation of severe TBI patients in the intensive care unit demonstrated significantly impaired neurologic outcome 3 and 6 months after injury in the hyperventilation group.²³ This led to the recommendation that routine hyperventilation be avoided in severe TBI.^{24,25} However, inadvertent hyperventilation early after injury remains a common problem and the impact of this transient period of hyperventilation on outcome has only recently been explored.

The cerebral arterial vasculature is extremely sensitive to changes in arterial carbon dioxide tension. Upon the induction of hypocapnia there is an immediate vasoconstriction of the cerebral arterioles, reducing cerebral blood volume (CBV), intracranial pressure (ICP), and, more important, cerebral oxygen delivery.²⁶ This leads to a shift in cerebral metabolism to an anaerobic state reflected by an immediate drop in jugular venous oxygen saturation and an increase in cerebral lactic acid production.^{27–29} While hypocapnia results in the favorable drop in intracranial pressure, the subsequent cerebral ischemia causes secondary injury to the traumatized brain (Fig. 18.1).

Positive-pressure ventilation may cause additional secondary insults by increasing intrathoracic pressure, thus decreasing venous return to the heart. This decrease in preload, especially in the patient with concomitant hemorrhagic volume loss, may manifest as systemic hypotension, further exacerbating secondary brain injury. This decrease in venous return may paradoxically cause increased ICP by causing venous congestion in the jugular venous system.^{30,31} Animal models of low blood flow states, such as hemorrhagic shock or cardiac arrest, have demonstrated significant impairment of hemodynamics associated with hyperventilation.^{32–35} Recently, results of an animal

FIGURE 18.1. Physiology of the cerebrovascular response to changes in arterial carbon dioxide tension (PaCO₂). As PaCO₂ increases, there is cerebral vasodilatation, which may increase cerebral blood flow but at the expense of increased intracranial pressure. As PaCO₂ decreases, vasoconstriction leads to decreased intracranial pressure but at the expense of impaired cerebral blood flow.

study assessing cerebral perfusion during hemorrhagic shock and varying ventilation rates reported significant compromise of cerebral perfusion and oxygenation at a rate of 12 breaths per minute that was not evident at 6 breaths per minute.³⁶

Most prehospital providers ventilate patients with bag valve devices with 100% oxygen connected to either a face-mask or directly to an endotracheal tube or other supraglottic airway. Many of these bags have a volume in excess of 1,200 mL. Uncontrolled bag ventilation can easily lead to inadvertent hyperventilation early after injury. Davis et al. have reported that three quarters of recorded end-tidal CO₂ values for intubated TBI patients were <30 mm Hg in the prehospital setting.³⁷ Likewise, Thomas et al. have reported end-tidal CO₂ readings of <25 mm Hg in one third of patients and <30 mm Hg in two thirds of patients transported by prehospital air transport.³⁸ There is some variability among prehospital systems, however, as in Seattle we observed that only 18% of intubated trauma patients arrived with an arterial carbon dioxide tension (PaCO₂) <30 mm Hg.²²

A recent study suggests that intubated trauma patients arriving to the emergency room have improved outcome if the arrival PaCO₂ is within the range of 30 to 35 mm Hg.²² In a subsequent study, patients who were able to achieve a target ventilation range as reflected by a PaCO₂ of 30 to 39 mm Hg while in the emergency department (ED) had a significantly better outcome than those not able to achieve this range even after exclusion of patients who were severely hypercapnic (PaCO₂ >50 mm Hg).²¹ For patients with a severe TBI as defined by a Head Abbreviated Injury Scale (AIS) score of 4 to 5, patients in the target range had a significant survival advantage (mortality odds ratio [OR] 0.33, 95% confidence interval [CI] 0.15–0.75). Furthermore, patients who arrived, based on their prehospital ventilation, outside the target range appeared to benefit from correction to the target range while in the ED. These studies emphasize the importance of tracking serial arterial blood gas results during ED ventilation of intubated TBI patients.

In light of these data, some authors have advocated the use of end-tidal CO₂ monitoring in the prehospital environment to minimize inadvertent hyperventilation.^{39,40} While assessment of end-tidal CO₂ is important to confirm endotracheal tube placement^{41,42} and monitor for tube dislodgement, it is less reliable as a marker of ventilation status. Impaired perfusion secondary to hypovolemic shock or impaired pulmonary gas exchange due to thoracic injuries can have significant effects on the end-tidal CO₂ values. In a recently completed study, the correlation between PaCO₂ and end-tidal CO₂ was very poor (R² 0.277 for a cohort of intubated trauma patients managed in the ED).⁴³

Circulation. The most common cause of death during the first hour after injury is hemorrhage. Therefore, after establishment of a patent airway and adequate air exchange, the next priority is support of the circulation. Direct pressure usually controls obvious external hemorrhage. There are a number of new topical agents designed to promote clot formation, which can be used in conjunction with direct pressure.^{44,45} Studies are ongoing to determine the optimal product. For extremity injuries where direct pressure is not adequate to control the hemorrhage, recent data from the military experience in Iraq support that tourniquets should be considered as a life-saving maneuver.^{44,46} To initiate resuscitation, one or two large-bore IV lines may be placed in the upper extremities en route to the trauma center. However, placement of lines must not delay transport unless the patient is undergoing a complex extrication or is more than 30 minutes from a trauma center.⁴⁷ The standard of care in the prehospital setting for hypotensive patients is volume replacement and rapid transport to a trauma center. Historically, the pneumatic antishock garment was also used in this setting but has been largely abandoned based on data demonstrating increased mortality particularly

in patients with thoracic trauma.⁴⁸ However, the pneumatic antishock garment is still occasionally used as a splint for combined pelvic and lower extremity injuries.

The appropriate volume and type of fluid used for initial resuscitation of the hypotensive trauma patient remains controversial. Recent experimental and clinical evidence raises the possibility that internal hemorrhage from major vascular injuries should not be treated with IV fluid infusion until the bleeding can be controlled in the operating room.⁴⁹ In the hypotensive state, major vascular injuries have a chance to clot and temporarily stop hemorrhaging; however, if IV volume restores normal blood pressure, the clot can dislodge and the rate of bleeding can increase significantly. However, the clinical data supporting this approach are based on a single trial that focused on patients with penetrating torso trauma and with a short transport time to the trauma center.⁴⁹ The role of limited volume resuscitation in blunt trauma is unknown and could be particularly harmful to patients with TBI. Currently the standard resuscitation fluid for trauma patients is a crystalloid solution of either lactated Ringer solution or normal saline. Several recent studies have suggested that hypertonic saline solutions may be even more beneficial as the initial resuscitation fluid for hypotensive trauma patients and those with TBI; clinical trials are ongoing.^{50–52}

The controversy between the scoop-and-run philosophy and the field-resuscitation philosophy in seriously injured patients is best resolved by common sense. Patients who are a short distance from a trauma center should be expeditiously transported to the trauma center with attempts made during transport to obtain IV access. This strategy facilitates initiation of resuscitation on arrival at the trauma center. Alternatively, patients who are a long distance from a trauma center or who require long extrication times most likely will benefit from the administration of IV fluids. Similarly, the goal is an acceptable blood pressure (~90 to 100 mm Hg), not necessarily normal and obviously not hypertensive. Current standardized training programs (BTLS, PHTLS) for EMS personnel suggest that, at minimum, a trauma patient who does not require extrication should be assessed, treated, and packaged for transportation in less than 8 to 10 minutes.

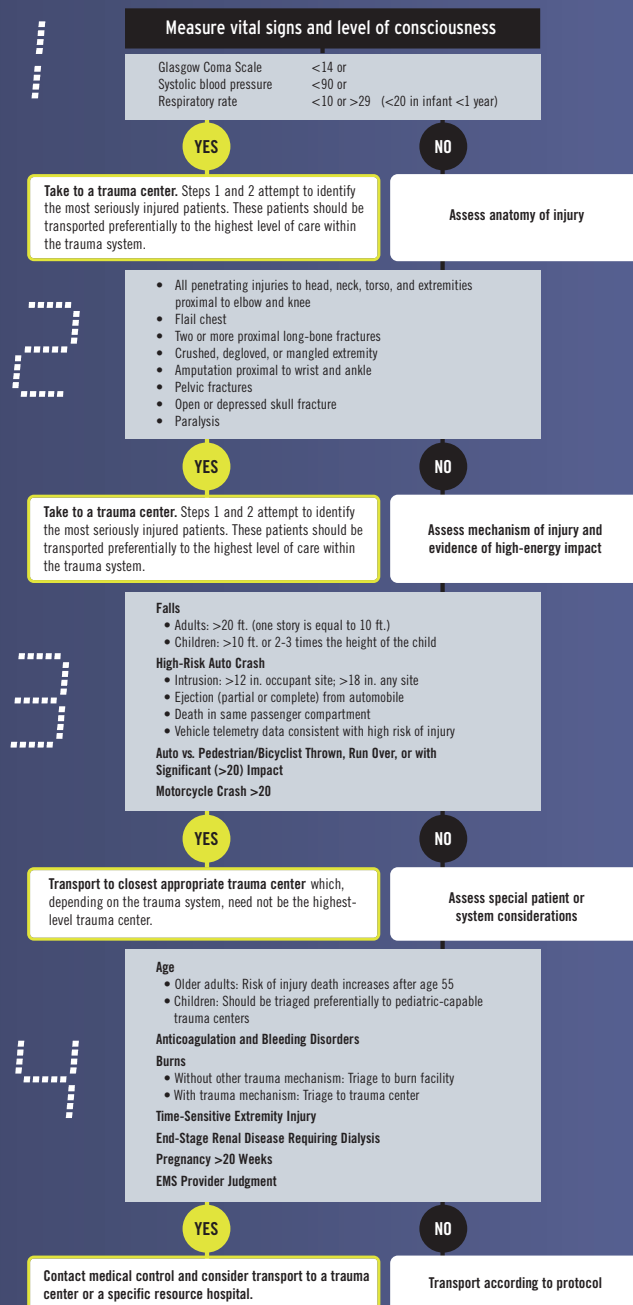

TRIAGE

Another key decision that needs to be made in the prehospital environment is to select the appropriate facility to receive the patient. The Centers for Disease Control and Prevention recently convened an expert panel to revise the Field Triage Decision Scheme for transport to a designated trauma center (Fig. 18.2).⁵³ This decision tree is based on four steps in the evaluation process. Step 1 involves an initial evaluation of physiologic status and level of consciousness including Glasgow Coma Scale (GCS) score, systolic blood pressure, and respiratory rate. Step 2 focuses on specific injury patterns likely to require trauma center care. Step 3 addresses the mechanism of injury, and Step 4 considers the extremes of age and other mitigating comorbidities. If at any point in the algorithm the patient meets the suggested criteria, then transport to a designated trauma center is recommended. This algorithm has been endorsed by the American College of Surgeons Committee on Trauma.

RESUSCITATION PHASE

Development of trauma centers and trauma systems has produced documented improvement in survival of multiply injured patients in numerous reports.^{54–58} Trauma centers are hospitals committed to the total care of the trauma patient, 24 hours a day. Multidisciplinary trauma teams consist of

emergency physicians, general and orthopedic surgeons and neurosurgeons, critical care nurses, and diagnostic technicians. After notification of a major injury from the scene, the trauma team assembles in a specially equipped resuscitation room prior to the patient's arrival. On arrival, care is immediately transferred to the trauma team, and the resuscitation phase is initiated without a delay. If feasible, seriously injured patients should bypass hospitals without these resources and be taken to the nearest trauma center.

Many patients have relatively minor injuries that do not require mobilization of this expensive team and resources. Therefore, an important function of a trauma system is to allow communication between prehospital personnel and the trauma center to identify those patients who will benefit from trauma center care. A written prehospital report describing the mechanism and extent of injury, vital signs, GCS score, and treatment started by the prehospital personnel should also be provided. These details alert the trauma center team to look for specific injury patterns based on mechanism of injury and guide further workup. Assessment and treatment then follow a logical sequence based on nationally standardized protocols using the Advanced Trauma Life Support (ATLS) format.⁵⁹

Trauma Team Composition

- 4 The trauma team consists of members from different disciplines, each of whom sees the patient from a particular point of view. Of necessity, the team must have a single "captain of the ship" whose responsibility it is to organize and prioritize treatment efforts. In a well-orchestrated team, the team leader integrates and coordinates several tasks simultaneously. In most level 1 and 2 trauma centers, the team captain is a general surgeon trained in trauma care. In the ideal situation, the trauma surgeon should be present when the patient arrives. In many rural and nonacademic level 3 trauma centers, the initial team captain is an emergency physician, with a general surgeon assuming the role on arrival. Academic institutions with both emergency medicine and surgical residency programs have the obligation of training both specialties to assume the role of trauma team leadership.

Although responsibilities vary between institutions, anyone involved in the resuscitation of trauma patients must master several procedures: all types of airway management, including cricothyroidotomy; establishment of vascular access through both percutaneous and open approaches; decompression of the pleural space using needle or tube thoracostomy; and decompression of the pericardial space by pericardiocentesis, subxiphoid window, or emergency thoracotomy.

Primary Survey: Initial Assessment

- 5 The first priority of the trauma team is to repeat the assessment of the airway, breathing, circulation, and level of consciousness of the patient. This assessment is referred to as the *primary survey*. Although in reality the primary survey is performed in a simultaneous fashion, it is described here in its individual components and their appropriate priorities.

The first priority is reassessment of the airway. Airway obstruction often responds to simple maneuvers such as suctioning, chin lift, jaw thrust, or placement of an oropharyngeal airway. Protection of the cervical spine with in-line immobilization is imperative during these maneuvers. Persistence of respiratory insufficiency requires endotracheal intubation. Unsuccessful intubation necessitates emergent cricothyroidotomy. Occasionally, the anatomy does not allow cricothyroidotomy, as can occur with laryngeal fracture. In these cases, a formal tracheotomy must be performed. After an airway is established, a physician auscultates the chest to confirm air exchange, confirms return of carbon dioxide via the endotracheal tube, and

obtains a chest radiograph to ensure proper tube position with the tip proximal to the carina. Appropriate placement of endotracheal tubes inserted in the prehospital setting should also be confirmed at this time.

The next priority is to ensure adequate ventilatory exchange by rapid auscultation of both lung fields and assessment for mechanical factors that may interfere with breathing. These factors include compression of the lung from hemothorax, pneumothorax, or visceral herniation; loss of chest-wall stability from flail chest; lung damage from pulmonary contusion; and airway obstruction from aspiration. A dramatic presentation with cyanosis, intense respiratory effort without air movement, distended neck veins, and lack of breath sounds on chest auscultation indicates that a tension pneumothorax is present. Clinical diagnosis of tension pneumothorax requires immediate needle thoracostomy followed by chest tube thoracostomy. Sucking chest wounds should be sealed with an occlusive dressing secured on three sides to function as a flap valve. Most other problems become evident on the initial chest radiograph and are relieved by chest tube insertion, suctioning, or repositioning of the endotracheal tube. The optimal position for chest tube insertion is the midaxillary line at the fifth or sixth interspace, avoiding the axilla, the large muscles of the back and chest, and the breast. Insertion of a finger into the chest before chest tube placement ensures entry into the pleural space and provides the opportunity to search digitally for defects in the diaphragm.

After establishment of an airway, ventilation, and appropriate pleural drainage, the next priority is assessment of the patient's circulatory status. Blood pressure, pulse, skin perfusion, temperature, capillary refill, mental status, presence of breath sounds, and neck vein distention are all useful clinical indicators of hemodynamic status. The first issue is to establish whether the patient is in hypovolemic shock and, if so, to determine the source of hemorrhage. Circulatory collapse in the injured patient is almost always caused by hypovolemia secondary to hemorrhage. Occasionally, concurrent heart disease, spinal cord injury, or cardiac tamponade may contribute. The mainstay of treatment for hypotension in the injured patient, regardless of cause, is volume resuscitation with crystalloid solution and, if hypotension is persistent, packed red blood cells (RBCs). A lack of response to IV infusion of 2 L of lactated Ringer solution indicates significant, ongoing hemorrhage and necessitates immediate blood transfusion.

Effective resuscitation from hemorrhagic shock requires both restoration of intravascular volume and control of hemorrhage. Most hypotensive patients are already compensating maximally on arrival in the ED and many have ongoing hemorrhage. The less responsive a patient is to initial volume resuscitation, the more urgent is the need for hemorrhage control. One need not wait for a response to resuscitation before taking the patient to the operating room. Another situation that requires vigilance is the cool, pale patient with relatively normal vital signs. These patients are compensating maximally and have a normal blood pressure because of intensive peripheral vasoconstriction. However, this compensatory mechanism is of only limited duration, and such patients require immediate rapid volume infusion, blood transfusion, and operative control of bleeding. A similar trap exists for patients with the mangled extremity syndrome or multiple open fractures. Patients may have lost significant blood volume at the injury scene. Before resuscitation, there may be relatively little hemorrhage from the open wounds; however, initiation of IV fluids may increase blood pressure and cause vasodilation, resulting in increased hemorrhage. These patients require immediate volume resuscitation and operative control of their wounds.

The final priority in the primary survey is a brief neurologic evaluation to assess the components of the GCS (Table 18.1). The GCS is scored by assessing eye opening, verbal responses, and motor responses with a maximal (normal) score of 15. In addition, pupillary size, reactivity and equality of the two, and

TABLE 18.1 **DIAGNOSIS****GLASGOW COMA SCALE (GCS)**

the presence of other lateralizing signs are assessed. Mental status may improve in response to volume resuscitation; however, a patient with a GCS score of 8 or less is assumed to have a significant brain injury. In this case, aggressive resuscitation, including appropriate adequate ventilation (see discussion under prehospital care, breathing), restoration of circulating volume, and the provision of adequate oxygenation, is an important consideration.

ED resuscitative thoracotomy is an aggressive, desperate attempt to save a dying patient. The dramatic return to full consciousness of a clinically dead patient after release of a pericardial tamponade from a stab wound to the heart provides complete justification for ED thoracotomy to those who have witnessed it. However, the widespread use of the technique in all patients arriving without vital signs has resulted in an extremely low survival rate at a very high cost. At first glance, the cost of an unsuccessful ED thoracotomy would seem to be nothing more than that of sterilizing the instruments and the physician's time. Many times, however, vital signs are temporarily restored, and the patient dies in the operating room or in the intensive care unit after massive blood transfusion and the use of considerable resources. Even worse is the rare patient who survives in a permanent vegetative state. The cost of the care for these patients must be included in any cost-benefit analysis. In addition, the risk of injury to a caregiver with viral contaminated blood or other infectious agents is unnecessary.

Boyd et al.⁶⁰ performed a meta-analysis of 24 reports concerning the outcome of ED thoracotomy. They found that the overall survival rate after ED thoracotomy was 11% (264 of 2,294 patients). There were no survivors among patients with no signs of life at the trauma scene. Signs of life were defined as supraventricular electrical activity, pupillary reaction, and agonal respirations. In addition, there were no neurologically intact survivors among blunt trauma patients who were without signs of life on arrival in the ED. Considering these findings, the researchers proposed an algorithm that would indicate ED thoracotomy for penetrating trauma only if the patient had signs of life at the scene and had lost signs of life less than 5 minutes before arrival in the ED. Blunt trauma

patients would be allowed ED thoracotomy only if the patient had signs of life on arrival in the ED. For patients who meet these criteria and lose cardiac function, airway placement and fluid resuscitation are initiated simultaneously with, or are immediately followed by, left anterior thoracotomy, pericardiotomy, and internal cardiac massage (Algorithm 18.1).

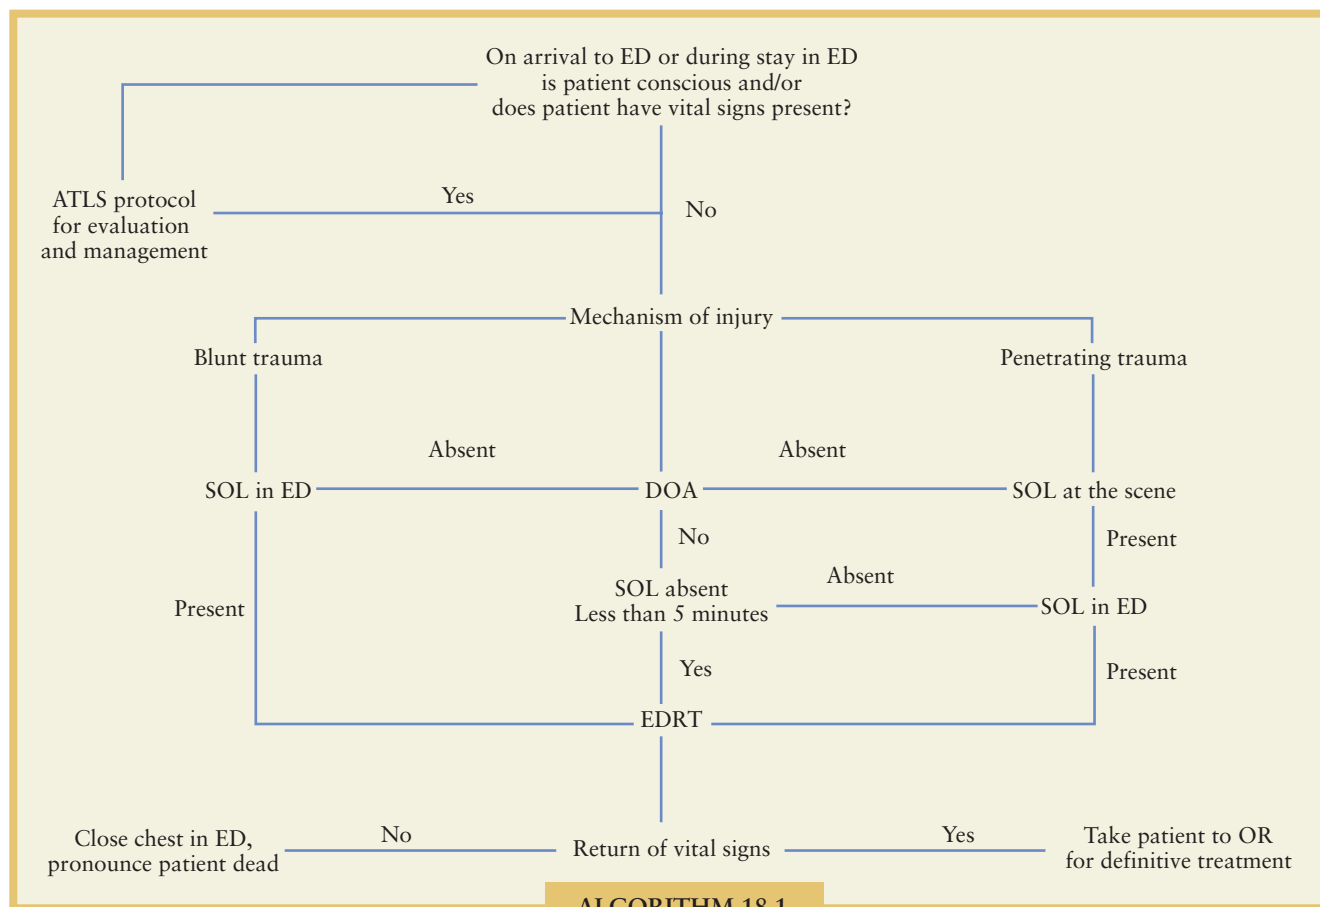

Secondary Survey

The secondary survey is directed at specific identification of suspected and unsuspected injuries. It consists of a thorough physical examination that includes observation and palpation of the entire body for evidence and characterization of injury. However, performance of the secondary survey depends on the results of the primary survey and the patient's response to initial resuscitative efforts. The secondary survey for a patient in hemorrhagic shock unresponsive to initial resuscitative efforts during the primary survey consists only of rapid identification of the bleeding site and rapid transport to the operating room for definitive control of hemorrhage. At the other end of the spectrum, a completely stable patient with relatively minor injuries undergoes a complete physical examination with confirmatory laboratory and radiographic tests before initiation of the treatment phase. The secondary survey can be interrupted at any time if a patient's status deteriorates. Adjuvants to the secondary survey include radiographic examinations and laboratory testing. For the purposes of description, the secondary survey is discussed by its individual components.

Head and Face. The head-to-toe examination usually begins with palpation of the skull and the head to identify hematomas, lacerations, and fractures. Scalp lacerations can cause significant blood loss and should be closed with a full-thickness running suture to provide hemostasis. Potential ocular injuries are assessed by testing visual acuity, pupillary function, and ocular range of motion. A funduscopic examination is important to identify increased intracranial pressure, vitreal hemorrhage, or retinal detachment. The findings of ecchymosis over the mastoid process, hemotympanum, otorrhea, rhinorrhea, or periorbital ecchymosis often indicate basilar skull fracture. Thorough palpation and attempts to displace facial bones identify step-offs or instability associated with facial fractures. Reassessment of the airway and a careful bimanual examination of the oral cavity identify loose teeth as well as mandibular and maxillary fractures. Bleeding from nasal fractures may require posterior and anterior packing for hemostasis; transnasal posteriorly placed Foley catheter balloons often work well to stanch bleeding.

Neck. Examination of the cervical region is conducted while axial immobilization of the cervical spine is maintained. The cervical collar is removed and the neck is examined for tracheal deviation, subcutaneous emphysema, hematomas, lacerations, or distended jugular veins. The posterior cervical spine is palpated to elicit tenderness or other signs of obvious fracture. Evidence of laryngeal fracture includes subcutaneous emphysema, tenderness, "step-off" (distortion of the thyroid and cricoid cartilage), and voice change. The presence of a fractured larynx is a relative contraindication to endotracheal intubation because of the possibility of extending the injury or creating a false passage leading to loss of the airway. Patients with suspected laryngeal fractures should be taken to the operating room immediately for formal tracheotomy. Carotid pulses are assessed, and bruits or expanding hematomas that may be suggestive of carotid artery injury are identified.

Penetrating injuries should not be probed, cannulated, or explored past the platysma because uncontrollable hemorrhage may ensue if a clot is dislodged from a major vascular injury. Wounds that have penetrated the platysma are evaluated either by formal operative exploration of the neck or by

ALGORITHM 18.1. Emergency thoracotomy for penetrating trauma. (Adapted from Boyd M, Vanek VW, Bourguet CC. Emergency room resuscitative thoracotomy: when is it indicated? *J Trauma* 1992;33:714–721.)

some combination of angiography, triple endoscopy (pharyngoscopy, laryngoscopy, and esophagoscopy), radiographic contrast study, computed tomography (CT) scan, and observation.⁶¹ Injuries encompassing the area from the cricoid cartilage to the angle of the mandible are usually explored. Angiography is mandatory for injuries between the cricoid cartilage and the clavicle and for injuries between the angle of the mandible and the base of the skull. Radiographic evaluation of the cervical spine should include anteroposterior, lateral, and odontoid views. A CT scan is often used to evaluate suspected bony injuries, and careful flexion and extension films may be necessary to rule out potentially unstable ligamentous injuries of the cervical spine.

Chest. The chest wall is inspected for evidence of instability and for lacerations, including sucking chest wounds, abrasions, and contusions. Auscultation is performed to identify hemothorax or pneumothorax, and palpation is used to elicit tenderness that may be associated with rib fractures. As has been mentioned, tension pneumothorax can be identified by cyanosis, tracheal deviation, distended neck veins, lack of breath sounds, and inability to move air. Tension pneumothorax causing cardiopulmonary collapse is a clinical (not radiologic) diagnosis that requires immediate treatment by needle thoracostomy followed by chest tube insertion.

Virtually all other life-threatening and potentially life-threatening chest injuries are diagnosed or suspected on chest radiography. Hemothorax is identified by opacification of a hemithorax and is treated by chest tube thoracostomy. Most

pulmonary parenchymal bleeding stops with reexpansion of the lung and complete evacuation of the pleural space. Additional chest tubes should be placed, if necessary, to completely evacuate the thorax. However, thoracotomy is indicated if the initial blood loss exceeds 1,500 mL or if the rate of ongoing blood loss shortly following injury exceeds 200 to 300 mL/h in an adult.⁶² Pulmonary contusion is identified by radiographic findings of an irregular interstitial pattern or frank consolidation in the lung parenchyma. The clinical manifestations of pulmonary contusion vary from mild dyspnea to overt pulmonary failure with development of acute respiratory distress syndrome. The magnitude of the injury is rarely appreciated during the initial evaluation, and it is important to follow up with serial blood gas determinations and a repeat chest radiograph at 6 hours.

All patients with chest trauma should have an electrocardiographic (ECG) evaluation and continuous monitoring during the first hour in the ED. If the ECG is normal, the patient may be discharged, if otherwise appropriate. Patients with ECG changes during the initial hour may have a blunt cardiac injury and should be monitored for at least 24 hours. If there is any sign of myocardial failure, the patient should undergo echocardiography. Most blunt cardiac injuries are self-limited and require only monitoring and treatment of significant dysrhythmias during the first 24 to 48 hours. Rarely, patients have manifestations of overt myocardial failure and require full support, including an intra-aortic balloon pump.

Patients with rapid deceleration blunt injuries to the chest may sustain a transection of the thoracic aorta. The chest

radiograph should be evaluated for widening of the mediastinum (more than 8 cm on a 40-inch anteroposterior chest radiograph), apical capping of the lung with extrapleural blood, tracheal displacement, depression of the left main-stem bronchus, loss of the aortic window, deviation of the nasogastric tube, and loss of the paraspinous stripe. Each of these findings suggests the presence of a mediastinal hematoma, which is often associated with a transection of the aorta. Patients with a significant mechanism of injury and suspicion of mediastinal hematoma on chest radiography should undergo diagnostic evaluation with either CT angiography or arch aortography to rule out transection of the aorta. In some centers, transesophageal echocardiography has also been reported to identify these injuries.

Evidence of a ruptured diaphragm on chest radiograph includes the presence of the nasogastric tube or bowel above the normal plane of the diaphragm. If the patient has a diagnosis of ruptured diaphragm and respiratory distress, consideration should be given to careful placement of a chest tube. Placement of the chest tube to water seal instead of suction minimizes the negative intrathoracic pressure and prevents further herniation. These patients should undergo expeditious exploratory laparotomy to repair the defect and address the commonly associated intra-abdominal injuries.

Management of penetrating injuries to the chest depends on the trajectory of the missile. Wounds confined to one lung or pleural cavity are usually treated by chest tube placement alone, with reexpansion of the lung. If the missile may have traversed the mediastinum, further evaluation is necessary, potentially including bronchoscopy, esophagoscopy, and aortography. Echocardiography is used to rule out pericardial blood and heart injury. False-negative studies have occurred when blood in the pericardium decompresses through the injury into the pleural space. However, echocardiography may be a sufficient screening tool if there are no clinical signs or symptoms of cardiac injury and no hemothorax. Gunshot wounds below the nipple line, the upper limit of diaphragm excursion, place the abdominal cavity at risk and thus require abdominal exploration as well.

Abdomen. The abdominal examination should attempt to determine whether there is a significant injury requiring surgical intervention. Although physical examination is often accurate and reliable, it can be misleading in 20% to 30% of patients.⁶³ This inaccuracy is particularly true in patients who are obtunded from head injury, alcohol, drug use, or shock. If patients are hemodynamically unstable, it is important to determine rapidly whether free intraperitoneal hemorrhage is responsible for the hypotension. Diagnostic peritoneal lavage (DPL) or the focused abdominal sonogram for trauma (FAST) accomplishes this goal rapidly and safely. Both are reported to be extremely reliable in the hemodynamically unstable patient.^{64,65} Both studies are operator dependent, however, and the choice of the best approach may depend on local hospital resources. DPL has the advantage of also being very sensitive for hollow viscus injury and thus is often preferred in the setting of a seatbelt sign with increased concern for bowel perforation.

DPL is considered grossly positive if more than 10 mL of blood is freely aspirated after catheter insertion. If less than 10 mL of blood or no blood is aspirated, 1 L of warmed crystalloid solution is infused into the peritoneum and then drained. A sample of the drained fluid is sent to the laboratory for RBC and leukocyte count, amylase and bilirubin level, and Gram stain for the presence of bacteria. DPL is considered microscopically positive if the RBC count is higher than 100,000/mL. If the goal is to find the source of hemorrhage in a hypotensive patient, then a grossly positive DPL pinpoints the abdomen as at least one source, and the patient should undergo immediate laparotomy. In contrast, a microscopically positive DPL indicates

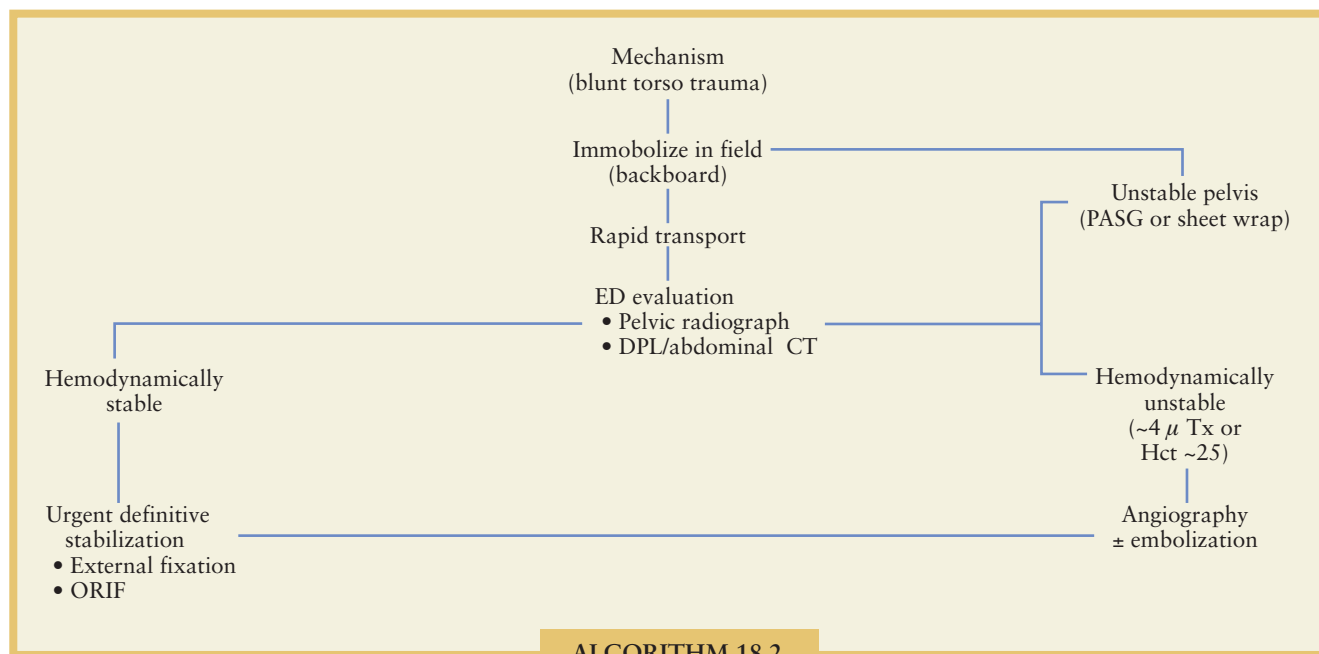

intra-abdominal injury that may eventually require laparotomy, but the major source of hemorrhage causing the hypotension is likely elsewhere (chest or pelvis).⁶⁶

In the hemodynamically stable patient, the lack of specificity of the DPL and FAST could lead to nontherapeutic and therefore unnecessary laparotomies. For this reason, CT has become routine for the evaluation of the abdomen in hemodynamically stable patients. Injuries that often have subtle findings during the first several hours after injury but may be found on a delayed CT scan include duodenal rupture, pancreatic transection, and blunt rupture of the intestine. Similarly, laboratory evaluations that may be helpful include liver enzyme levels and serial serum amylase levels with serial determinations in high-risk patients.

The workup for patients with penetrating abdominal injuries depends on the missile. Gunshot wounds to the abdomen are an indication for exploratory laparotomy because 90% to 95% of these patients have intra-abdominal injuries. The occasional patient with a tangential subcutaneous wound can be evaluated by laparoscopy or even CT to determine whether peritoneal penetration injury has occurred.⁶⁷ Stab wounds to the abdomen are often evaluated initially by local exploration of the wound. If the wound traverses the anterior fascia, then the patient can be evaluated by DPL or laparoscopy and should undergo exploratory laparotomy if the results are positive. A lower threshold for a positive RBC count is often set for stab wound injuries because the DPL is designed simply to confirm peritoneal penetration and not significant bleeding. Stab wounds to the flank and back are best evaluated by a triple-contrast CT scan and serial observation.^{68,69} CT scan findings that mandate exploratory laparotomy include significant retroperitoneal hematoma, free air, extravasation of contrast material, and free intraperitoneal fluid.

Pelvis. After evaluation of the abdomen, the pelvis is assessed by physical examination. The bones of the pelvis are palpated gently to elicit tenderness that could indicate fracture. Evidence of instability of the pelvic ring warrants placement of a sheet around the pelvis to reduce the pelvic volume and minimize venous bleeding in the retroperitoneum. This procedure can be performed in the field or on arrival in the ED. In some systems the pneumatic antishock garment is used for this purpose, but better reduction can often be achieved with a simple bed sheet tied around the iliac crests. The genitalia should be inspected for scrotal hematoma or blood at the urethral meatus, which indicates probable urethral transection. A bimanual pelvic examination in women identifies evidence of vaginal laceration, indicating an open pelvic fracture. A rectal examination is performed to identify blood indicative of bowel injury and, occasionally, a mobile, "floating" prostate, which indicates urethral transection. Evidence of a free-floating prostate, blood at the urethra, or scrotal hematoma should prompt a retrograde urethrogram before placement of a bladder catheter is attempted. All patients sustaining significant blunt torso trauma should undergo plain radiography of the pelvis to diagnose potential pelvic fracture.

If the patient is hemodynamically unstable, the pelvic fracture must be considered a potential source of hemorrhage. This consideration is important because pelvic fracture bleeding is retroperitoneal and rarely controllable at exploratory laparotomy. Venous bleeding is treated by reducing the volume of the pelvis, and arterial bleeding should be evaluated and treated by early angiography and embolization. Some authors have reported success with operative preperitoneal packing when angiography is not immediately available and the patient is rapidly exsanguinating.⁷⁰⁻⁷² If the patient is hemodynamically stable, the pelvic fracture should be evaluated further with additional plain radiographs and CT scans (Algorithm 18.2).

ALGORITHM 18.2. Emergency management of pelvic fractures. PASG, pneumatic antishock garment; ED, emergency department; DPL, diagnostic peritoneal lavage; CT, computed tomography; Tx, transfusion; Hct, hematocrit; ORIF, open reduction internal fixation.

Extremities. Finally, the extremities are evaluated for open wounds with potential sources of hemorrhage or occult open fractures. Evaluation of pulses may indicate vascular injury. Palpation and passive range-of-motion tests diagnose potential long-bone fractures, dislocations, and ligamentous injuries. Dislocations require prompt reduction, especially if there is any evidence of neurovascular compromise. Penetrating wounds to the extremities necessitate evaluation for potential vascular injury by palpation of pulses, auscultation for bruits, and recognition of expanding hematomas. Proximity wounds can be evaluated by duplex ultrasound scan or arteriography. With any injury, development of a compartment syndrome due to bleeding or associated edema should also be considered.

SUMMARY

The ideal trauma system consists of a prehospital care team that quickly and safely transports an injured patient to a trauma center where a multidisciplinary trauma team immediately begins resuscitation of the patient. Treatment of immediately life-threatening injuries begins during transport and continues after arrival at the trauma center. Rapid initial evaluation, followed by a more detailed secondary survey, allows identification of injuries while therapy is simultaneously begun. The primary survey focuses on identification and simultaneous treatment of life-threatening injuries, including airway obstruction, mechanical factors in the chest that impair ventilation, and control of hemorrhage. The next priority is assessment and intervention for neurologic injuries including traumatic brain injury and spinal cord injury. Once these issues have been addressed, the secondary survey is performed to identify all other injuries. The secondary survey is interrupted as necessary to treat life-threatening and limb-threatening injuries as they are identified. If interruption becomes necessary, the secondary survey is completed at a later time.
